Our studies concerned a special class of stimulus patterns—one-dimensionally periodic distributions of light which, because of their alternating light and dark bar structure, are called grating stimuli (Fig. 1 inset). The visual detectability of such grating stimuli is frequently specified by the minimum (or threshold) value of contrast level at which the grating can just be detected, with the contrast defined as $(I_{max}-I_{min})/(I_{max}+I_{min})$, I_{max} and I_{min} being respectively the maximum and minimum illumination levels present in the grating stimulus pattern. It has been shown that the threshold contrast level for detection of a grating increases transiently after adaptation to a similar grating of high contrast[3–5]. This adaptation effect is observed only when the test and adaptation gratings are of similar spatial frequency (that is periodicity) and when they are oriented in near parallel directions. The adaptation effect can be studied by presenting both test and adaptation gratings to the same eye[5], or by presenting them one to each eye[6], and both methods yield essentially the same results. We measured the grating adaptation effect with the test and adaptation gratings, matched in orientation and spatial frequency, presented to one eye and a further grating stimulus, which we call the conditioning grating, presented to the other eye (Fig. 1 inset). The results show that when the conditioning grating is of spatial frequency, f_{cg}, in the approximate range 1–4 cycles per degree, it suppresses the adaptation for all spatial frequencies, f_{ag}, of the test and adaptation gratings, except when f_{ag} is equal to f_{cg}. With the observer's head in the normal upright position, this suppression effect is observed only when all the gratings are orientated in a vertical direction and only when the conditioning and adaptation gratings are presented to different eyes.

The experimental arrangement of the visual fields is illustrated in Fig. 1 (inset). The grating patterns were produced by laser interference methods[6,7] and were in all cases sinusoidally modulated grating patterns of 100% contrast. The adaptation effect was measured in terms of Δ, equal to $\log I - \log I^1$, where I is the mean threshold illumination level of the 100% modulated test grating required for its detection after adaptation to the adaptation grating and I^1 the corresponding illumination level following adaptation to a uniform field. The illumination level of the uniform field and the mean illumination level of the adaptation grating were set equal at 4.5 log trolands, thus ensuring that both stimuli produced the same mean retinal adaptation condition. At the start of each measurement, the observer viewed the adaptation grating for 4 min and was instructed to scan the field during the periods of adaptation to ensure uniform retinal adaptation. As the grating adaptation effect is of short duration[5], the test and adaptation gratings were then alternated for periods of 3 and 20 s, respectively, the cycle being repeated until the observer obtained the threshold illumination level, I, for detection of the test grating. A similar procedure, in which the adaptation grating was replaced by a uniform field of the same mean illumination level, was used to determine I^1. The conditioning grating was presented in coincidence with the adaptation grating (Fig. 1 inset) and the observer's head was fixed by means of a dental clamp with the interocular direction horizontal. Data were obtained for three observers, all of whom gave substantially similar results, and the data presented here refer to E.W. who made the most extensive observations.

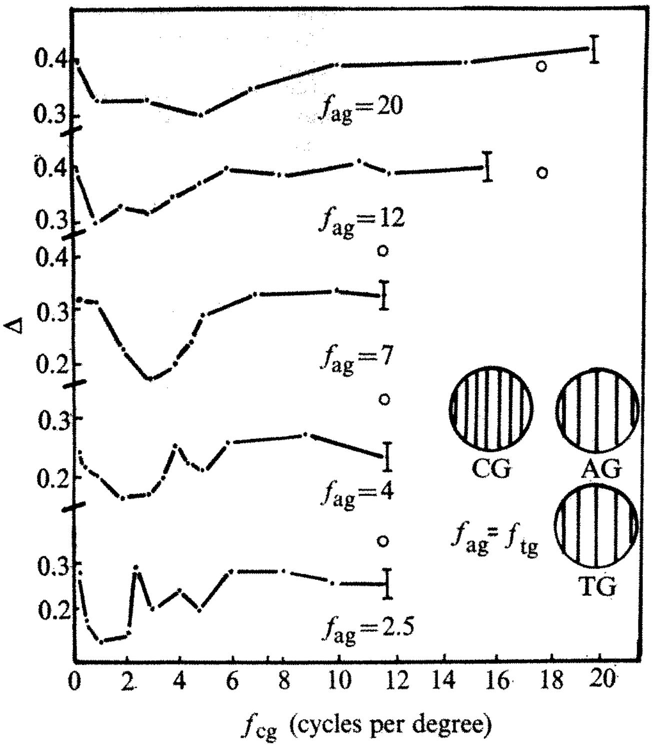

Fig. 1 Values of Δ plotted against the spatial frequency, f_{cg}, in cycles per degree of the conditioning grating. Plots are given for five spatial frequencies, f_{ag}, of the test and adaptation gratings and the values of f_{ag} corresponding to each plot are given in cycles per degree to the right of the data points. Experimental points, denoted by the full circles, are the mean of 10 observations, and typical standard errors are denoted by the vertical error bar given with the highest frequency point of each plot. All other standard error values were similar in amplitude to those defined by the bars. For each value of f_{ag}, Δ was also determined in the absence of the conditioning grating, and the values obtained in this way are plotted as open circles to the right of each plot. All grating stimuli were of wavelength 632.8 nm and the illumination level of the adaptation and conditioning gratings was 4.5 log trolands throughout. All gratings were orientated in a vertical direction. The inset shows the appearance of the visual fields in the two eyes. During periods of adaptation, the conditioning grating, CG, was presented to the left eye and the adaptation grating, AG, to the right eye. The test grating, TG, was presented in isolation to the right eye. All gratings fields were 30°.

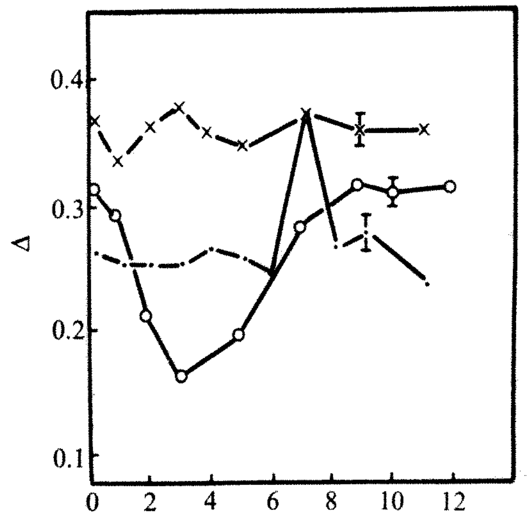

Fig. 2 Values of Δ plotted against the spatial frequency of the conditioning grating, f_{cg}, in cycles per degree. All values refer to test and adaptation gratings of spatial frequency 7.0 cycles per degree. Open circles refer to the stimulus configuration shown in Fig. 1, that is, with all gratings orientated vertically, the adaptation and conditioning gratings presented simultaneously to the right and left eyes, respectively, and the test grating presented to the right eye. Crosses refer to a similar stimulus configuration, but with all gratings oriented in a horizontal direction. Full circles refer to the arrangement in which the adaptation and conditioning gratings were both presented to the same eye as the test grating. All data points are the mean of 10 observations and typical standard error values are denoted by the vertical error bars. All stimuli were of wavelength 632.8 nm and the illumination level of the adaptation and conditioning gratings was 4.5 log trolands. $f_{ag} = f_{tg}$ = 7 cycles per degree.

The results obtained with the grating bars orientated in a vertical direction are given in Fig. 1, values of Δ being plotted against f_{cg}, the spatial frequency of the conditioning grating. Data are given for a number of values of f_{ag}, the common spatial frequency of the test and adaptation gratings, and the values of Δ obtained in the absence of the conditioning field are also given for each value of f_{ag}. These data show that there is a small decrease in Δ, relative to the value obtained in the absence of the conditioning stimulus, over much of the range of f_{cg}. For values of f_{cg} in the approximate range 1–4 cycles per degree, however, there is a large decrease in Δ, implying that the adaptation effect is suppressed in the presence of the conditioning grating. An exception to this is observed when the conditioning and adaptation gratings have the same spatial frequency, for example, at f_{cg} equal to 2.5 cycles per degree for the data referring to f_{ag} equal to 2.5 cycles per degree. When the experiment was repeated with the gratings oriented horizontally, however, the data showed that for all values of f_{cg}, except f_{cg} equal to f_{ag}, Δ is reduced by about 0.1 relative to its value in the absence of the conditioning grating (full circles in Fig. 2). Measurements with the gratings set at various angles between vertical and horizontal established that the grating adaptation effect is suppressed only for vertical and near-vertical orientations of the grating lines (Fig. 3). Further experiments were performed in which the adaptation and conditioning grating were both presented to the same eye as the test grating, all three gratings being orientated vertically. A typical set of data is given in Fig. 2 (crosses), values of Δ being plotted against f_{cg}, the spatial frequency of the conditioning stimuli. The large reduction in Δ for f_{cg} in the range 1–4 cycles per degree found when the adaptation and conditioning gratings are presented to different eyes, does not occur when they are presented to the same eye. Thus the suppression of the grating adaptation effect by a low frequency conditioning grating is specifically associated with binocular interaction. No low frequency inhibition of the kind seen in Fig. 1 is found when the adaptation grating is presented to one eye and the test grating to the other[6]. The inhibition of the grating adaptation effect associated with the conditioning grating seems, therefore, to arise from an interaction between the suprathreshold adaptation and conditioning gratings during their simultaneous presentation to different eyes.

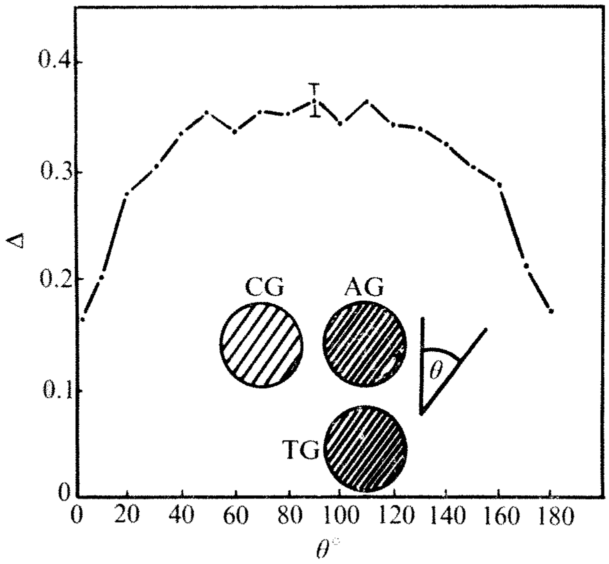

Fig. 3 Values of Δ plotted against θ, the angle at which the gratings were orientated from the vertical. The test and adaptation gratings were of spatial frequency 7.0 cycles per degree and the conditioning grating was of spatial frequency 3.0 cycles per degree. All points are the mean of 10 observations and the vertical error bars denote typical mean errors. The stimulus wavelength was 632.8 nm and the illumination level of the adaptation and conditioning gratings was 4.5 log trolands. f_{cg} = 3 cycles per degree; f_{tg} = f_{ag} = 7 cycles per degree.

The restriction of the binocular suppression effect to gratings orientated in a vertical direction suggests that it is involved in the stereoscopic fusion mechanism. Suppression of signals from all but matched low frequency components of images presented to the two eyes would facilitate stereoscopic fusion of low frequency elements of the visual field. Investigation of disparity-sensitive neurones in cat and monkey has revealed response features consistent with the characteristics of the binocular interaction described here. Thus, in the monkey, the long axis of the bar-shaped receptive fields of disparity neurones are preferentially orientated vertically[2], and in the cat, binocular inhibitory interaction is apparent in the responses of such neurones[8]. Stereoscopic fusion effects in human vision associated with periodic structures can be demonstrated more readily for low frequency than for higher frequency structures[9,10]. The spatial frequency range of inhibitory binocular interaction found in our experiments corresponds approximately to the range of preferred spatial frequencies revealed in these studies on stereoscopic fusion of periodic structures. We have considered the possibility that the observed binocular suppression of the grating adaptation effect is a result of binocular rivalry in perception of the adaptation and conditioning grating stimuli. Neither the spatial frequency specificity of the suppression effect (Fig. 1) nor its restriction to near-vertical orientations of the gratings is, however, characteristic of binocular rivalry observed during our experiments. Other experiments also indicate that the grating adaptation effect is not modified by binocular rivalry[11].

We thank Dr G. J. Burton for helpful discussion and interferometric equipment. We also thank Mr R. Dowdney for help.

Suckling stimulation induces aggression in virgin female mice

THE aggression shown by parturient mammals of various species towards strange conspecifics[1,2], referred to as "maternal aggression", ostensibly serves to protect the young. Although much is known about the aetiology of other forms of aggressive behaviour, no information is available about the mechanism responsible for maternal aggression. We found recently that suckling stimulation may be important in the initiation of aggressive behaviour in parturient mice[3]. Animals whose nipples were removed before parturition and that were given foster young each day after delivery did not become aggressive. Moreover, we could not induce aggression in virgin female mice by exposing them continuously to foster young. A reason for this may be that virgin females, because of the lack of nipples, which usually develop during pregnancy, did not receive suckling stimulation from foster young. We hypothesised that if nipple growth were induced in virgin females, they would be able to receive suckling stimulation and thus would exhibit aggressive behaviour comparable with that of parturient animals. The results presented here confirm the hypothesis by showing that suckling stimulation induces aggression.

Eighty-five 60–65-d-old virgin female Rockland–Swiss mice (RS) were divided into four groups. One group of 24 mice, after bilateral overiectomy under ether anaesthesia, received a regimen of hormones that we had found to induce nipple growth. We gave 19 daily subcutaneous injections of 0.02 μg oestradiol benzoate dissolved in 0.02 ml sesame oil and 500 μg progesterone in 0.02 ml oil. (The synergistic action of oestrogen and progesterone in mice is confirmed by the fact that little or no nipple growth occurs in response to injections of either oestrogen or progesterone.) Another group of 20 virgin females was ovariectomised and administered oil for 19 d, while another 19 mice were sham ovariectomised and treated daily for 19 d with oil. A group of 22 mice was left intact and mated with RS males. Each animal was housed singly in an 11 × 7 × 5 inch polypropylene cage, the floor of which was covered with pine shavings. The animals had free access to food and water and were maintained on a 12 h light/12 h dark cycle with lights on between 0600 and 1800. Testing was between 0700 and 0900 and injections were given between 1000 and 1100.

The virgin mice were tested for aggression 24 h after the final injection of oil or hormone. Animals permitted to mate were tested on day 19 of gestation. An adult RS male was placed into the cage of each animal and left for 3 min or until a fight was observed. A fight was defined as 20 s of continuous biting and chasing. Immediately after the aggression test, each

*Animals in experiment 1 were killed after they fought in two successive tests.

†Animals in experiment 2 were given 10 aggression tests. The data are derived from only the animals that fought.

Experiment 1: aggressive behaviour of RS female mice that were either mated (parturient), ovariectomised and primed with oestradiol benzoate and progesterone to induce nipple growth (OVX+OB+P), ovariectomised and treated with oil (OVX+Oil), or sham ovariectomised and given oil (S–OVX+Oil). Aggressive behaviour was scored before exposure to pups (on the last day of hormone or oil treatment or on day 19 of gestation) and on each succeeding day for 10 d after presentation of foster young or until fights were displayed on 2 successive days. Experiment 2: aggressive behaviour of RS females that were mated and either thelectomised (parturient–THEL) or sham thelectomised on day 19 of pregnancy (parturient–S–Thel) and of ovariectomised hormone-treated mice either thelectomised (OVX+OB+P—THEL) or sham thelectomised (OVX+OB+P–S–THEL) on the day after the last hormone injections.

animal was presented with five 3–8-d-old RS foster young. (The pregnant animals were allowed to deliver and their young were removed before presenting them with foster young.) On the next morning each animal was observed for maternal behaviour for 15 min, after which a test for aggression was conducted. Immediately after the aggression test the nipples of each animal were examined (red and distended nipples indicated that the female had received suckling stimulation) and the pups were removed and replaced by five other 3–8-d-olds. This procedure was continued for a further 9 d or until an animal exhibited aggression on two successive tests. The animals were killed at the termination of testing to determine whether milk was present in the mammary tissue.

Every animal exhibited the complete repertoire of maternal behaviour including retrieval of pups, licking of the pups' ano-genital region, and the assumption of the nursing posture. This confirms reports that non-pregnant and non-lactating mice display maternal behaviour[4].

None of the animals fought when tested before exposure to foster young (Table 1). Instead, they sniffed and groomed the male intruder. After exposure to young, 12 of 22 parturient mice and 12 of 24 hormone-treated virgin females were aggressive. The absence of aggression in approximately 50% of the animals in each of these groups is not unusual for we consistently find that 40–50% of parturient RS females are not aggressive[5]. In contrast, only one of 20 oil-treated, ovariectomised and one of 19 oil-treated, sham-ovariectomised virgins fought. Both oil-treated groups differed significantly from the hormone-treated animals and from the parturient animals with respect to the number that were aggressive (χ^2, $P < 0.01$).

Aggression typically occurred on the first test after exposure to pups, although a few animals began to fight on the second or third test. The topography of the fighting behaviour of the hormone-treated virgins was indistinguishable from that of the parturient animals. The initial latency to attack averaged 4 s with the attacks consisting of bites to the neck and flanks of the intruder male. Tail rattling and ano-genital sniffing were observed during fights but not before the initial attack. Intruders, never initiating a fight nor fighting back in response to attack, generally assumed submissive postures.

Daily inspection of the parturient and hormone-treated animals after exposure to pups revealed red and distended nipples. In both groups the pups attached themselves to the nipples such that they could maintain contact with the adult when the latter was lifted by the tail. In contrast, red and distended nipples and attachment were never observed in either of the groups injected with oil. Only the mammary glands of the parturient animals contained milk.

To verify further that the hormone regimen induced nipple growth, six more animals were placed into each treatment group. They were killed either after 19 d of hormone or oil treatment or on day 19 of gestation. The results are summarised in Table 2. On the average, nipple length was 100% and the base diameter was 30% greater for hormone-treated than for oil-treated virgin females. For pregnant animals, the same measures were 200% and 50% greater than those of oil-treated virgins.

Table 2 Average length (mm) and base diameter of a representative nipple of different animals

Group	Average length	Base diameter
Parturient	1.40±0.05*†	0.66±0.06*†
OVX+OB+P	0.99±0.07*	0.55±0.14*
OVX+Oil	0.49±0.08	0.43±0.08
S–OVX+Oil	0.47±0.13	0.41±0.06

Animals were either mated (parturient), ovariectomised and hormonally primed with oestradiol benzoate and progesterone (OVX+OB+P), ovariectomised and treated with oil (OVX+Oil), or sham ovariectomised and given oil (S–OVX+Oil).

*Significantly different (Fisher's least significant difference test, $P < 0.05$) from OVX+Oil and S–OVX+Oil.

†Significantly different from OVX+OB+P.

The findings show that virgin female mice can be induced to show aggression comparable with that of parturient animals by producing nipple growth and presenting them with young. Hormone exposure did not induce fighting directly, for treated animals were never aggressive before exposure to young. Suckling stimulation, therefore, may be essential for the initiation of aggression. To corroborate this we assessed the effect of the suckling stimulus.

Eighty 60–65-d-old virgin female RS mice were divided into four equal groups. Two groups were ovariectomised and given the hormone regimen described above. The nipples of one group were then removed (thelectomy) under ether anaesthesia on the day after the last hormone injection. The other group was sham thelectomised: 1-mm incisions were made along the ventral midline. The two remaining groups were left intact and mated with RS males. One of these groups was thelectomised on day 19 of pregnancy and the other was sham thelectomised. Testing and fostering were as before, except that animals were allowed to complete all 10 aggression tests.

All animals were comparable with respect to maternal behaviour. None was aggressive before exposure to young (Table 1). After exposure to pups, 13 of 20 sham-operated parturient mice and 12 of 20 sham-thelectomised hormone-treated virgins were aggressive compared with four of 20 thelectomised parturient animals and two of 20 thelectomised hormone-treated virgins. The thelectomised groups differed significantly from their sham-operated counterparts with respect to the number that fought ($P < 0.02$). The sham-thelectomised groups did not differ in terms of time taken to become aggressive or the average number of fights exhibited. Daily examination of both sham-operated groups revealed red and distended nipples, indicating that they had received suckling stimulation.

Thus hormone-treated virgins respond to thelectomy in a manner identical to that of parturient mice with thelectomy, significantly reducing the proportion of animals that are aggressive. The data agree with others which demonstrate the attenuating effects of thelectomy on maternal aggression in parturient mice[3].

Finally, 12 hormone-treated virgins and 12 parturient animals that fought the intruder on the third day of exposure to foster young were deprived of their foster young immediately after the fighting test and were retested 24 h later. If fighting did not occur on retesting, five foster young were placed into the cage and, beginning 24 h later, daily aggression tests and daily fostering of young were carried out until fighting recommenced. Animals that fought 24 h after removal of foster young continued daily aggression tests in the absence of the young. As soon as fighting was no longer exhibited, foster young were reintroduced and daily tests were conducted until fighting began.

All animals stopped fighting after pups were removed and resumed fighting when they were replaced. The hormone-treated virgins and the parturient animals did not differ in terms of the number of days after removal required to terminate fighting (range = 1–4 d, median = 1.0 d) or the number of days of pup replacement required to re-establish fighting (all within 1 d). Each animal had red distended nipples and nipple attachment after replacement of foster young. Thus the aggression of both hormone-treated and parturient mice can be eliminated by removing the suckling stimulus and re-established by reintroducing that stimulus.

The fighting behaviour induced in female mice hormonally primed to induce nipple growth could have been a response to chronic stress, produced by chronic suckling by deprived young, rather than a response specific to the suckling stimulus. We do not believe that this is the case, however, because virgin females and lactating mice whose pups had been removed did not attack a male after 24 h of intermittent electric shock to the paws. Moreover, virgins and lactating mice deprived of young did not attack a male after chronic application of painful stimulation to the nipples. Thus fighting in hormone-treated virgin female mice seems to be a response specific to the suckling stimulus.

Our data show that suckling not only supplies nourishment to the young but also affects the relationship between the mother and other adult members of her species. Suckling stimulates the release of hypothalamic and pituitary hormones[6], alters the rate of synthesis of hypothalamic monoamines[7], and changes the firing patterns of hypothalamic neurones[8]. One or more of these changes may induce aggressive behaviour in lactating mice.

Transmission of *Trypanosoma rotatorium* from frogs to white mice

ALTHOUGH the trypanosome *Trypanosoma rotatorium* Mayer 1843, lives in the blood of frogs (*Rana esculenta* and *R. temporaria*) it does not have a pathogenic effect on them. Since no information is available about the mass incidence of these parasites in the blood of homoeothermic animals, we have tried to infect white mice with *T. rotatorium* in order to study the development of infection in these hosts.

Our experimental group consisted of 100 male and female white laboratory mice, strain ICR, from 3 weeks to 3 months old, which had been standardised both microbiologically and parasitologically (specific pathogen-free). Blood from young frogs (0.4–0.6 ml) diluted in 0.9% NaCl was administered intraperitoneally so that the final infective dose was 500 trypanosomes per animal. For controls we used 50 mice aged 3 weeks to 3 months which were given blood from uninfected frogs diluted in saline (2:1 v/v); 25 of them were injected with 2.5 mg of hydrocortisone twice a week for 3 weeks. The criterion for termination of incubation was the first appearance of trypanosomes in the peripheral blood of the mice. Dry blood smears were stained by the standard Giemsa method.

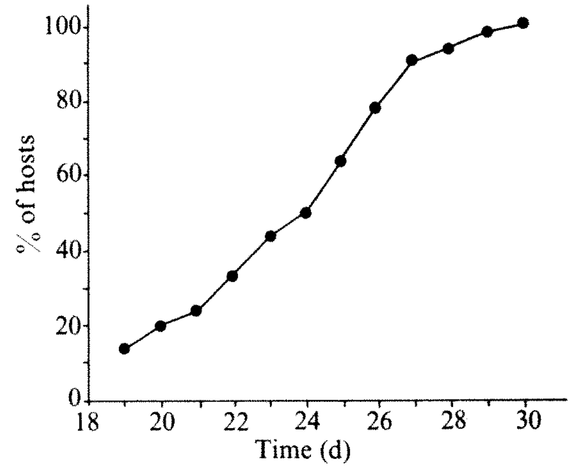

Fig. 1 The first incidence of *Trypanosoma rotatorium* in the blood of the individual mice is dependent on time.

Infection developed slowly with an incubation period of 18–30 d. There was considerable variation in the first appearance of trypanosomes in individual mice (Fig. 1). On day 24 of infection, trypanosomes were present in the blood of 50% of mice, 6 d later they were present in all hosts (100 mice).

The slender body of the trypanosomes, 10.6–18.7 μm long and 1.3–5.0 μm wide, ended in a short, obtuse rostrum. The oval nucleus was in the middle of the body and the blepharoplast was near its end. The undulating membrane passed into a short, free flagellum whose length did not exceed one-tenth of the body length (Fig. 2). Numerous dividing trypanosomes appeared in the blood of the mice. Division was binary and of the standard type. Multiple division in crithidia was not observed (Fig. 3).

No overt signs of disease were evident before the first appearance of trypanosomes in the blood of infected animals. An increase in the number of blood parasites was manifest in

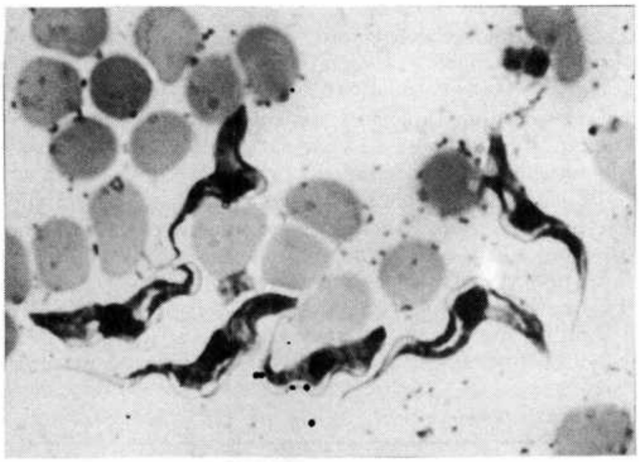

Fig. 2 *T. rotatorium* in the blood of a white laboratory mouse. Dry smear stained with Giemsa (× 1,600).

loss of appetite, loss of weight, bristling of the fur and general restlessness. The animals died within 2–5 d of multiplication of the parasites in the blood (maximum incidence 100,000 trypanosomes per ml of blood).

Since no information was available about transmission of trypanosomes from poikilotherms to homoeotherms our findings with mice had to be compared with published data on parasites from tadpoles and frogs[2-6]. During the development of infection in the frog, the morphology of trypanosomes changes considerably[2-6]. Trypanosomes from tadpoles and young frogs are slender, with a long flagellum[5,6]. Those multiplying in the blood of mice, however, reached about half the size of those multiplying in frog blood.

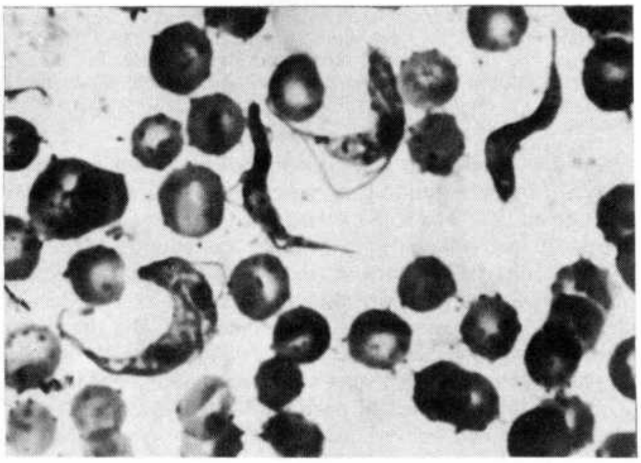

Fig. 3 In the left corner at the bottom *T. rotatorium* dividing in blood of white mouse. Stained with Giemsa (× 1,600).

A form of trypanosome that is often described from the blood of adult frogs is large and almost immobile, with a striped pellicle and a short undulating membrane which does not continue in a free flagellum[2,4-6]. This form has never been found in mice.

Compared with *T. duttoni*, one of the most frequent trypanosomes of rodents[1,7], *T. rotatorium* from mice was more slender, and its rostrum was shorter. There were differences in the location of the blepharoplast which is near the nucleus in *T. duttoni*, and the length of the free flagellum which reaches a half to two thirds of the body length of *T. duttoni*. In contrast to *T. duttoni*, *T. rotatorium* never produced multiple forms in mouse blood[1,7].

Thus the morphology of trypanosomes from mice is closest to that of trypanosomes from tadpoles and young frogs, except for the larger body size of those in the poikilothermic hosts and the very short free flagellum of those in mice.

Study of haemopoietic microenvironment *in vitro*

THE concept of the haemopoietic inductive microenvironment as first proposed by Curry and Trentin[1] has been amply confirmed by experiment. One salient feature of this concept relates to the role of the mouse spleen in promoting erythropoiesis rather than granulopoiesis. For example, in the clonal growth of transplanted bone marrow cells, the spleens of the irradiated host mice have erythroid and granuloid colonies in a ratio of 3, whereas the ratio is 0.5 in the bone marrow of the same hosts[2,3]. Other data show that there is a positive effect of splenic tissue, rather than a negative effect of bone marrow, on erythroid colony growth[3]. We have tested this concept using cocultures of mouse spleen and bone marrow cells and have found that

Table 1 Effect of NS and XS cells on marrow erythropoiesis

	Haemoglobin ^{59}Fe (±s.d.) (c.p.m.)	Δ c.p.m.	% of marrow control
Marrow cells − E	17±6	—	100
Marrow cells + E	232±16	215	1,260
NS cells − E	3±2	—	18
NS cells + E	17±3	14	100
Marrow + NS cells − E	50±10	—	294
Marrow + NS cells + E	286±45	236	1,680
XS cells − E	0	—	0
XS cells + E	0	0	0
Marrow + XS cells − E	150±11	—	880
Marrow + XS cells + E	491±18	341	2,890

E, erythropoietin. Cells were cultured in 0.2 ml samples, as previously described[6], in the wells of culture dishes. The medium, *p*H 6.9, consisted of 65% NCTC-109 containing 30 mM morpholinopropane sulphonic acid (MOPS), 30% foetal calf serum, 5% mouse serum containing 73 nmol of ferric nitrate per ml, and gentamicin (0.5 mg ml^{-1}). Both the foetal calf serum and the mouse serum were heat-inactivated at 56 °C for 30 min before use. Six replicate cultures were established per group. A sheep plasma preparation of erythropoietin (16 mU) with a potency of 200 U per mg of protein was added to the appropriate cultures dissolved in 1 µl of 0.1% bovine serum albumin, 0.15 M NaCl. The wells were sealed with sterile plastic adhesive sheets. After 20 h of incubation at 37 °C the wells were opened and 20 µl of ^{59}Fe-labelled mouse serum (0.2 µCi) were added to each; the wells were then resealed and incubated for 5 h, after which incorporation into haemoglobin was measured as before[6,7]. Spleens were removed aseptically from 10–14-week-old BDF$_1$ female mice. XS cells were prepared from mice which had received 900 R of whole-body X rays 3 d before use. Marrow cells were cultured at 2.9×10^6 per well; NS and XS cells were cultured at 2.7×10^6 per well. Spleen cells were dispersed by forcing splenic tissue through a sterile stainless steel screen (60 mesh) into 70% NCTC-109, 30% foetal calf serum. Remaining cell clumps were broken up by repeated passage of the suspension through a 26-gauge needle. The cells were washed once in phosphate-buffered saline before appropriate dilution in complete medium. Essentially the same results were obtained when the spleen cells were dispersed by digestion with collagenase.

Table 2 Effect of freezing and thawing of irradiated spleen cells

	Haemoglobin ^{59}Fe (±s.d.) (c.p.m.)	Δ c.p.m.	% of marrow control
Marrow cells − E	5±3	—	100
Marrow cells + E	112±15	107	2,240
XS cells − E	0	—	0
XS cells + E	0	0	0
Marrow + XS cells − E	52±2	—	1,040
Marrow + XS cells + E	197±14	145	3,040
Frozen-thawed XS cells − E	0	—	0
Frozen-thawed XS cells + E	0	0	0
Marrow + frozen-thawed XS cells − E	19±3	—	380
Marrow + frozen-thawed XS cells + E	85±14	66	1,700

Culture conditions and procedure were as outlined in Table 1. In the preparation of frozen and thawed XS cells, the cells in 25 μl of complete medium were added to appropriate wells and the dishes were placed on a mixture of crushed dry ice and ethanol for 15 min. They were then incubated at 37 °C for 20 min before the bone marrow cells were added in 175 μl of complete medium. Marrow cells were cultured at 3.2×10^6 per well; XS cells were cultured at 1.7×10^6 per well.

phenomena related to the haemopoietic inductive microenvironment can be studied *in vitro*.

Table 1 shows that spleen cells in culture augment haemoglobin synthesis by marrow cells *in vitro* in two ways. These may be characterised as an effect on baseline haemoglobin synthesis and an effect on erythropoietin-induced haemoglobin formation. Cells from the spleens of normal mice (NS cells), as well as from the spleens of mice given 900 R of whole-body X radiation 3 d earlier (XS cells), caused increased incorporation of ^{59}Fe into haemoglobin when they were added to marrow cell cultures. The effect on the baseline was almost three times greater with XS than with NS cells. Neither NS nor XS cells alone synthesised significant amounts of haemoglobin by the method used. In addition, XS cells but not NS cells caused a significant potentiation of the marrow cell response to erythropoietin, amounting to about 60% more stimulated haemoglobin synthesis than found with marrow cells alone. The NS cells showed a slight response to erythropoietin, but XS cells never did.

We attempted to determine whether intact XS cells were required for the observed effects. The data in Table 2 show that freezing and thawing of the cells reduced but did not abolish the effect on the baseline, and completely eliminated the effect on erythropoietin-induced haemoglobin synthesis. In fact, the frozen-thawed preparation caused a 38% suppression of the response to erythropoietin (Δ c.p.m.). This suppression is significant at the $P<0.02$ level.

Table 3 Effect of further irradiation of spleen cells on marrow haemoglobin synthesis

	Haemoglobin ^{59}Fe (±s.d.) (c.p.m.)	Δ c.p.m.	% of marrow control
Marrow cells − E	8±1	—	100
Marrow cells + E	77±5	69	963
XS cells − E	0	—	0
XS cells + E	0	0	0
Marrow + XS cells − E	40±3	—	500
Marrow + XS cells + E	155±7	115	1,940
XXS cells − E	0	—	0
XXS cells + E	0	0	0
Marrow + XXS cells − E	40±2	—	500
Marrow + XXS cells + E	170±11	130	2,120

Culture conditions and procedure were as outlined in Table 1. The XXS cells were prepared by irradiation of a sample of the XS cell suspension with 10,000 R of X rays just before culturing. There were 3.2×10^6 marrow and 1.8×10^6 spleen cells per well.

Additional X irradiation of XS cells *in vitro* with 10,000 R (XXS cells), immediately before they were added to the marrow cell cultures, enhanced the response to erythropoietin to a significantly greater extent ($0.02>P>0.01$) than did the single *in vivo* irradiation (Table 3). The effect on baseline haemoglobin synthesis, however, was the same with both XS and XXS cells, amounting to five times more incorporation.

The two effects (enhanced baseline synthesis and potentiation of response to erythropoietin) were distinguished further when species specificity was studied. Table 4 shows that baseline haemoglobin synthesis by rat bone marrow cells was increased 49% by mouse NS cells and almost 200% by mouse XS cells. In contrast, the response of rat marrow to erythropoietin was not affected by mouse NS cells and was depressed by mouse XS cells.

Table 4 Effect of mouse spleen cells on rat marrow erythropoiesis

	Haemoglobin ^{59}Fe (±s.d.) c.p.m.	Δ c.p.m.	% of marrow control
Rat marrow cells − E	47±11	—	100
Rat marrow cells + E	182±14	135	387
Mouse NS cells − E	0	—	0
Mouse NS cells + E	0	0	0
Rat marrow + mouse NS cells − E	70±7	—	149
Rat marrow + mouse NS cells + E	202±15	132	430
Mouse XS cells − E	0	—	0
Mouse XS cells + E	0	0	0
Rat marrow + mouse XS cells − E	140±9	—	298
Rat marrow + mouse XS cells + E	226±18	86	481

Culture conditions and procedure were as outlined in Table 1, except that bone marrow cells from male Sprague–Dawley rats (250–275 g) were used and rat serum was substituted for mouse serum. Marrow cells were cultured at 3×10^6 per well; NS and XS cells were cultured at 1.8×10^6 per well.

The data presented here permit several conclusions with respect to an understanding of the haemopoietic inductive microenvironment. (1) The role of the spleen in promoting erythropoiesis of mouse bone marrow cells can be studied *in vitro*. (2) Two different mechanisms seem to augment haemoglobin synthesis by splenic tissue. One concerns the existing level of haemoglobin formation by normal marrow cells; the second concerns the increase in response to added erythropoietin. (3) The action of normal spleen cells on baseline haemoglobin synthesis can be duplicated partially by cells which have been frozen rapidly and thawed, making it likely to be an effect of a cell constituent rather than of viable cells. (4) Mouse spleen cells can affect the baseline haemoglobin synthesis of rat marrow cells. (5) The action of either normal spleen cells or cells from the spleens of irradiated mice potentiates the action of erythropoietin on haemoglobin synthesis, but this effect is restricted to intact cells and may be species specific. Although it might be argued that the extent of erythropoietin-stimulated haemoglobin synthesis is maximal when rat marrow cells are incubated with mouse XS cells, so that an increase in the baseline will cause a necessary decrease in the erythropoietin effect, we have seen, in other experiments, much greater induced haemoglobin synthesis. This observation makes it more plausible that the decrease in c.p.m. from 135 to 86 (Table 4) represents a true suppression of erythropoietin action.

The nature of the cell constituent postulated above to be responsible for the action of spleen cells on baseline haemoglobin synthesis is unknown, and will be investigated further. Our evidence suggests that the second of the effects, that of potentiation of the response to erythropoietin, is mediated by intact cells. Bessis and Breton[4] have described a large cell, resembling a macrophage, around which erythroblasts are clustered. They have proposed that this cell acts as a "nurse cell" in normal erythropoiesis by facilitating iron transfer to the developing erythroblasts. This type of cell might be responsible for the effect we describe. Alternatively, the effect might be due to the type of radio-resistant cell that is found in spleen and is involved in the processing of antigen in the immune response[5].

Several proliferative phases precede maturation of IgG-secreting cells in mitogen-stimulated cultures

SEVERAL workers have shown that stimulation of mouse spleen lymphocytes by *E. coli* lipopolysaccharide (LPS) results in extensive proliferation of B lymphocytes and the rapid maturation of immunoglobulin M (IgM)-secreting cells[1–3]. Not all B lymphcytes that are stimulated to DNA synthesis and division by LPS, however, develop into high rate Ig-secreting cells[4,5]; dividing blast cells can give rise to large numbers of non-dividing small B lymphocytes with a high density of surface Ig and no detectable intracellular Ig pool[4]. In these respects such secondary cells are thought to resemble memory cells. Those cells which do develop into high rate Ig-secreting cells during a few days of culture are generally restricted to secretion of IgM[7,8]. We report here that in improved culture conditions, and dependent on repeated cycles of mitogenic stimulation, precursors to IgG and IgA as well as IgM-secreting cells can undergo the full maturation sequence. Our results suggest that one or more phases of resting cells are intermediates in this sequence.

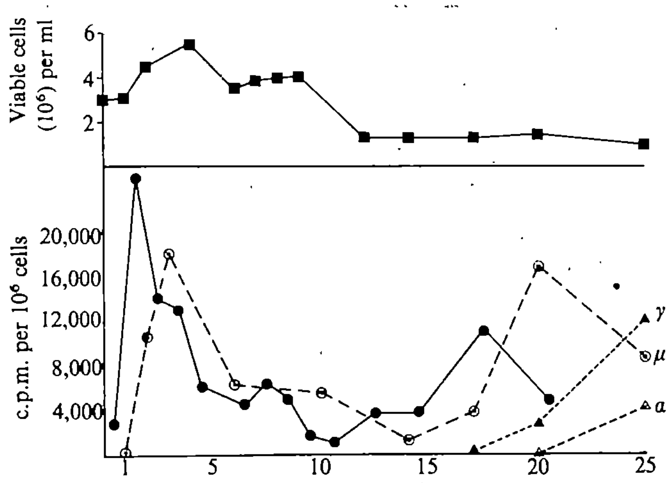

Fig. 1 DNA synthesis and Ig secretion in LPS-stimulated cultures. Spleen cells (CBA mice) were suspended, washed once and cultured at 3×10^6 cells per ml in RPMI 1640 medium (Biocult) supplemented with LPS (*E. coli* 055B, Difco, 10 μg ml^{-1}) 10% foetal calf serum (Flow), antibiotics and 6×10^{-5} M 2-mercaptoethanol (2ME). Culture dishes (60 mm) containing 5 ml were kept stationary at 37 °C in an atmosphere of 10% CO_2, 7% O_2 and 83% N_2. Every 3 d cells were sedimented (5 min at 240*g*) and resuspended in fresh, full medium and LPS. For ^{3}H-thymidine incorporation, duplicate 0.2 ml samples from the above cultures were incubated for 24 h at 37 °C with 1 μCi ^{3}H-thymidine (50 mCi mmol^{-1}) in microplates. The cells were filtered on Whatman glass fibre circles (GP/A), and washed with phosphate-buffered saline, trichloracetic acid, ethyl alcohol and ether[3]. Assessment of thymidine incorporation on microscale is justified; 4-h pulses in more recent experiments yield analogous results. For Ig secretion, cells sedimented from 0.6 ml of culture were incubated for 4 h in 0.4 ml of RPMI medium (containing only 2.5×10^{-5} M methionine), 10% foetal calf serum, 6×10^{-5} M 2ME and 20 μCi ^{35}S-methionine (> 100 Ci mmol^{-1}). The medium was then diluted with phosphate-buffered saline and methionine (1 mg ml^{-1}), cells were removed and the supernatant was clarified by high speed centrifugation. Ig was precipitated from half the supernatant using a polyvalent rabbit antiserum to mouse IgM and IgG and carrier Ig[8,9]. Ag/Ab precipitates, washed twice, were reduced and analysed by polyacrylamide gel electrophoresis as described in Fig. 2.

Mouse spleen lymphocytes were stimulated with LPS in the conditions described in the legend to Fig. 1. It is important for the long term maintenance of these cultures that medium be replaced every 3 d. The increase and then decline in cell number as well as the pattern of ^{3}H-thymidine incorporation and Ig secretion during 25 d are shown in Fig. 1. A high rate of ^{3}H-thymidine incorporation is observed on days 2 and 3 and followed on day 7 and again on day 17 by additional peaks of incorporation. Increases in cell numbers on days 4 and 8 reflect these high thymidine incorporation rates. The rate of Ig secretion increases to a maximum on day 3, after which it falls to a relatively low level. By day 20 the rate of Ig secretion is again very high (Fig. 1).

We have analysed the class of Ig secreted at various times in culture by fractionation of the Ig heavy chains on sodium dodecyl sulphate (SDS)–polyacrylamide gels.

Table 1 Induction of IgG secretion in T-cell depleted spleen

Spleen donor		Radioactivity (c.p.m. ml^{-1})†			Viable cells per ml ($\times10^{-6}$)	
		Day 19	28	31	19	28
Normal	μ Chains	8,470	38,060			
	γ Chains	2,730	20,620		7.0	1.5
T×B*	μ Chains	12,540	34,140	33,490		
	γ Chains	2,640	10,470	12,900	6.8	2.1

*(CBA×C57)F_1 mice were thymectomised, irradiated with 850 r. and reconstituted with foetal liver for 10 weeks. Spleen cells were treated with AKR anti-C_3H Thy. 1.2 and complement before culture[11].

†Radioactivity of secreted Ig heavy chains (^{35}S-methionine labelled) was analysed by electrophoresis after reduction of Ig precipitated with antiserum (see Fig. 2).

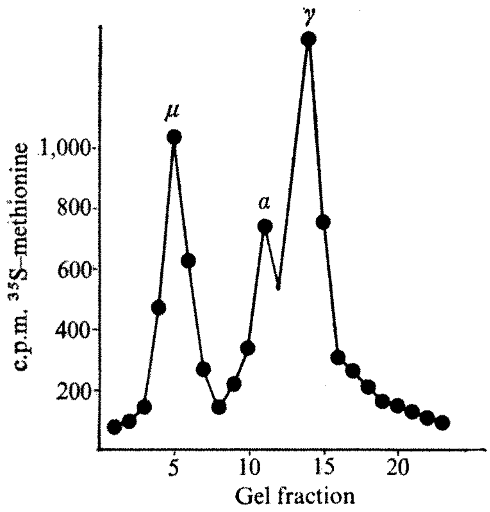

Fig. 2 Fractionation of secreted immunoglobulin heavy chains. ^{35}S-Ig secreted on day 25 (see legend to Fig. 1) was precipitated with antiserum to Ig, dissociated in 2% SDS, reduced overnight in 0.15 M 2ME at 37 °C in borate-buffered saline, and alkylated with iodoacetamide for 1 h at *p*H 8. Polyacrylamide gel electrophoresis was carried out as described by Maizel[10], gels were dried and then cut into 2-mm strips which were prepared for liquid scintillation counting by treatment with 0.5 ml H_2O_2 for 3 h at 70 °C. Internal markers for μ and γ chains were included on every gel and revealed by staining with Coomassie blue. In addition, labelled heavy chains of myeloma proteins confirmed the position of μ, γ and α chains.

A gel profile of reduced and alkylated Ig secreted into the culture medium during a pulse of ^{35}S-methionine on day 25 is shown in Fig. 2. Analysis on different days shows that only immunoglobulin of the IgM class is secreted early in the culture period, while late immunoglobulin secretion includes large amounts of IgG, some IgA and a new wave of IgM (Fig. 1). Cells fixed and stained for intracytoplasmic Ig using class-specific and fluorescent antisera (prepared by R. M. E. Parkhouse) have confirmed the presence of cells synthesising each of these Ig classes (unpublished results of M.Z. and R. M. E. Parkhouse).

Neither the activation of precursors nor the lag in maturation of the IgG-secreting cells depends on the presence of T cells, as shown by the similarity of results obtained using spleens from mice depleted of T cells, both *in vivo* and *in vitro*, or from normal mice (Table 1). The difference in amount of IgG secreted in the two types of culture is within the range of variation normally observed with different pools of spleen cells.

It has been shown[12] that the stimulation by antigen of cells producing specific IgG antibody in short term culture depends on the presence of a transient cell type which appears to be an intermediate between a long term memory cell and an antibody-producing cell. We have investigated whether this intermediate cell type responds to LPS and whether a transient pool of such cells in a normal spleen might account for the IgG response we have observed. Table 2 shows that these cells do respond to LPS and give comparable numbers of antibody-producing cells as in antigen-stimulated cultures. The peak of this response, however, is on day 5 and is easily differentiated from the larger LPS-stimulated IgG response detected by isotope incorporation and gel analysis on day 17. It is likely that this intermediate cell type is responsible for the reported[14,15] stimulation of a small number of IgG antibody-forming cells by mitogen in short term cultures.

Table 2 Specific anti-DNP-forming cells and IgG secretion

Additions	Day 5	7	10	13	17
	7S PFC/* culture				
None	530	20	20	20	—
DNP–KLH (0.1 μg ml^{-1})	3,360	1,080	170	40	0
LPS	2,300	300	620	545	30
	Secreted IgG (c.p.m. per culture)				
LPS	< 800	920	790	1,380	9,530

PFC, Plaque-forming cells. Radioactivity of secreted ^{35}S-methionine-labelled IgG was estimated as in Figs 1 and 2. Spleen cells were derived from mice primed and then boosted 8 d previously with DNP–KLH (dinitrophenol–keyhole limpet haemocyanin)[12]. Culture conditions were as described in Fig. 1.

* Specific indirect anti-DNP-forming cells were detected using horse red blood cells sensitised with trinitrobenzene sulphonic acid and then developing plaques with rabbit anti-mouse IgG[12,13].

The occurrence of a long lag period in LPS-stimulated cultures during which the level of ^{3}H-thymidine incorporation is low suggested that a non-proliferating cell might be an intermediate in the maturation of precursors to IgG and other late Ig-secreting cells. This was further investigated by the addition of bromodeoxyuridine (BUdR) to cultures at various times at a concentration (10 μg ml^{-1}) which on subsequent irradiation by means of a black lamp (300–400 nm), leads to the death of cells actively engaged in DNA synthesis. Only a few cells survived (less than 5%) when BUdR was present from 36 to 62 h after stimulation during the first wave of DNA synthesis, indicating that the dividing cells were killed. Precursor cells, however, did survive when a BUdR pulse was given on days 4 and 5 or 10 and 11, as shown by the maturation of large numbers of Ig-secreting cells later in the culture period (see below). It should be emphasised in this connection that stimulation of high rate IgG secretion depends on the re-addition of LPS to cultures when they are resuspended in fresh medium.

Table 3 Effect of BUdR on IgG secretion

Days	c.p.m. per ml culture* ^{3}H-thymidine	Cell no. per ml $\times 10^{-6}$	Ig† c.p.m. per ml culture μ chain	γ chain
Control 4	35,500	6.7	56,071	< 500
Control 7	9,250	3.0	54,417	4,455
Control 14		0.8	14,797	3,869
BUdR‡ 4	2,700	3.5	25,344	7,216
BUdR 7	48,250	1.9	4,356	< 440
BUdR 14		3.3	43,026	27,112

* 24-h pulse with 1 μCi ^{3}H-thymidine (50 mCi mmol^{-1}).

† Radioactivity of Ig secreted during a 4-h pulse with ^{35}S-methionine (see legends to Figs 1 and 2).

‡ BUdR (10 μg ml^{-1}) was added on day 3; after 24 h cells were collected and irradiated in the same volume as before in PBS for 20 min using a black lamp (Philips 20 W/08, 300–400 nm) before being resuspended in fresh medium. The same dishes were used throughout to avoid loss of adhering cells. Control cultures were handled in identical fashion in absence of BUdR.

An unexpected finding was that if BUdR is added and cultures are irradiated immediately after the first peak of ^{3}H-thymidine incorporation, precursor cells which survive initiate high rate IgG secretion and do so earlier than do controls. LPS-stimulated cells received a 24-h pulse of BUdR on day 3 of culture. ^{3}H-thymidine incorporation on day 4 immediately after the pulse is very low. By day 7, however, it has increased to a level many times greater than that observed in controls (Table 3). This effect is not due to a change in the specific activity of intracellular pools as a considerable increase in cell numbers occurs in parallel. Analysis of Ig secretion showed some early IgG (day 4) and large amounts of IgG on day 14. In these control cultures (washed and irradiated in the absence of BUdR) detectable IgG appeared earlier than usual (Table 3). Our interpretation of these experiments is that an inhibitory cell type which proliferates in LPS-stimulated cultures is eliminated by irradiation after the BUdR pulse. Secondary non-proliferating precursors quiescent during the pulse can then be activated sooner than would otherwise occur. Other experiments showed that cells present on day 9 of culture could block the activation of precursors to early IgM-secreting cells when mixed with freshly prepared spleen cells before, but not 27 h after, addition of LPS (M.Z., unpublished). Nevertheless, in view of the complexity of BUdR action[16,17], we cannot exclude the possibility that BUdR has a direct effect on precursor cells which speeds up further proliferation or leads to their rapid maturation. As all cells which are engaged in DNA synthesis are killed at the end of the pulse, this would have to be an effect on cells not proliferating during the pulse.

There have been two recent reports[5,18] that LPS treatment results, within 6–8 d, in the appearance of cells which synthesise IgG as detected by immunofluorescent staining of cytoplasmic Ig with specific antisera. In one case[5], these are described as immature, weakly staining lymphoblasts, while in the other[18], stronger staining denotes a more mature cell type in cultures initiated at low density. At such early times we detect low levels of IgG secretion in low density cultures set up according to Kearney and Lawton[18] and occasionally also in the conditions described here. High levels of IgG production, however, arise only late in our cultures and it is possible that several mitotic cycles are required before full maturation of these cells. The significance of initiating cultures at a low cell density is not clear, but may be a means of reducing inhibitory effects.

In conclusion, we have shown that precursors to IgG and IgA, as well as to IgM-secreting cells, can be activated by a mitogenic stimulus. After a proliferative phase they give rise to early IgM-secreting cells as well as to secondary non-proliferating cells. These secondary cells can be reactivated to undergo further proliferation and finally to mature to high rate IgG-, IgA- or IgM-secreting cells. An inhibitory cell type which also proliferates in these high density cultures may delay the reactivation of secondary cells. Neither the maturation of precursors to IgG production nor the inhibitory effects observed in LPS-stimulated cultures depends on the presence of T cells.

We thank P. Tilly for assistance and J. North for stimulating discussions.

Note added in proof: Additional evidence of production of IgG- or IgD-like molecules in low density cultures has been published[19].

Control of C3 levels in mice during ontogeny by a gene in the central region of the *H–2* complex

THE observation that differences in serum haemolytic activity in mice are controlled by the *H–2* complex[1], was followed by reports that in several mammalian species the levels of individual complement components (C), from both the classical and the alternative pathways, are influenced by genes located close to the major histocompatibility complex (MHC), (reviewed in ref. 2). The relationship between mouse Ss protein, serum levels of which are controlled by a gene in the central part of *H–2*, and human C4 (refs 3–5), highlights the association between MHC and the C system. The mechanism which underlies this association is largely unknown. In only one case (factor B) has a structural gene been identified[6]. We report here that the serum levels of C3 in mice during ontogeny are influenced by a gene in the central region of the *H–2* complex.

Breeding couples of inbred, congenic and congenic recombinant strains of mice were obtained either from commercial sources, or from Drs D. C. Shreffler and J. Stimpfling. Mice were bled in heparin-treated capillary tubes and plasma was stored at −70 °C. Antiserum to mouse C3 was obtained as before[7]. Immunoelectrophoretic analysis showed that this antiserum did not distinguish between native C3 and its degradation products C3b and C3d obtained by treating mouse serum with cobra venom factor. The specificity of this antiserum was ascertained by comparison with a monospecific antiserum to guinea pig C3 which cross reacted with mouse C3. In double diffusion in agarose against mouse serum, the lines given by the rabbit antiserum to guinea pig C3 and to mouse C3 coalesced in a reaction of identity. Simple radial immunodiffusion was performed as before[8]. Four different dilutions of a pool of normal mouse plasma were included in each plate as standards. Plates were incubated for 7 d at room temperature. When linear regressions were calculated for different plates for the relationship between areas of the rings compared with dilution of the standard antigen, coefficients of 0.999 or higher were obtained.

C3 levels in plasma of AKR/J mice were significantly higher than in DBA/2J until 4 weeks of age (ref. 8 and Table 1). At 9 weeks the differences were smaller and not significant. To assess the importance of the *H–2* complex in the control of C3 levels during development, segregation analysis and studies were performed with congenic and congenic recombinant mice which were 2 and 3 weeks old.

Table 1 summarises the results of segregation analysis, some of which have been reported already[8]. The 21-d-old progeny of the backcrosses (AKD2F$_1$ ♀ × DBA/2J or AKR/J ♂) or of the F$_2$(AKD2F$_1$ × AKD2F$_1$) mice were typed for *H–2* and classified as *k*/*k*, *d*/*k* or *d*/*d*. In all, 203 mice were examined. C3 levels were compared in all pertinent combinations and significant differences ($P<0.01$) in the expected direction were found in mice with different *H–2*. Furthermore, the differences in C3 levels between AKR/J and DBA/2J mice seem to be controlled by very few genes, for, with a single exception, there were no significant differences in C3 levels of mice with the same *H–2* type (Table 1). In ten comparisons, the only exception was that C3 levels of DBA/2J mice were significantly lower than those of the *d*/*d* progeny of F$_2$ mice. Measurements (not shown) of C3 levels at 15 d of age in the same backcrosses and F$_2$ showed an identical pattern of segregation. Body weights of mice with different *H–2* at 2–3 weeks of age were not different.

Table 2 shows that differences in C3 levels were detected among 21-d-old congenic mice of the B10 series which bear five unrelated *H–2* haplotypes. Plasma from 142 animals was analysed. $H{-}2^b$ and $H{-}2^d$ haplotypes are associated with small but significant differences in C3 levels. As expected from the results of the segregation analysis, $H{-}2^k$ mice have significantly higher C3 levels than $H{-}2^d$ mice. No differences were found between C3 levels of mice with $H{-}2^k$, $H{-}2^s$ and $H{-}2^f$ haplotypes.

The effect of allelic variation within the subregions of the *H–2* complex was studied in series of congenic and congenic recombinant mice with different S subregions of *H–2*. Each group consisted of a minimum of 20 mice, from three or more separate litters. Table 3 shows that C3 levels in A.AL strain were higher than in A strain. They differed only in the IC and S subregions. A.AL carries the *k* allele, and A carries the *d* allele in those subregions. In the C3H series, C3H.OH(S^d) and

H–2 type	AKR/J	DBA/2J	F_1	$F_1 \times$ AKR/J	$F_1 \times$ DBA/2J	$F_1 \times F_1$	F^x_y
k/*k*	0.86±0.13 (29)	—	—	0.81±0.09 (8)	—	0.91±0.14 (12)	$F^2_{46} = 1.57$ NS
d/*k*	—	—	0.70±0.07 (8)	0.74±0.06 (17)	0.69±0.09 (14)	0.76±0.12 (45)	$F^3_{80} = 2.58$ NS
d/*d*	—	0.53±0.06 (36)	—	—	0.58±0.09 (12)	0.68±0.10 (22)	$F^2_{67} = 23.4$ $P < 0.01$
F^x_y	$F^2_{70} = 100$ $P < 0.005$			$F^1_{23} = 53$ $0.025 > P > 0.01$	$F^1_{24} = 9.9$ $P < 0.005$	$F^2_{76} = 15.0$ $P < 0.005$	

Numbers not in parentheses represent relative concentration of C3 in plasma (mean±s.d.). Numbers of animals are given in parentheses. The differences or similarities in complement levels between groups of strains, or multiple groups of animals, were estimated by analysis of variance. In the F^x_y ratios, *x* represents degrees of freedom for genetic variation and *y* represents degrees of freedom for phenotypic variation.

C3H.OL(S^k) strains, which differ only in the S subregion, have small but significantly different C3 levels in the direction predicted from the segregation studies. B10.Br and B10.M(17R) are identical in the K, IA and IB subregions, and have different C3 levels; B10.Br is *k* in the IC, S and D subregions, and has higher C3 levels than B10.M(17R) which is *d* in IC and S subregions.

These comparisons show that the gene controlling C3 levels is located within or closely linked to the S subregion of *H–2*. Some additional observations are compatible with this hypothesis. (1) In the A/WySn-A.CA combination, the *f* allele in the S subregion is associated with higher C3 levels than the *d* allele, and in the C3H series, the *d* and *k* alleles of S have higher C3 levels than the *b* allele. These findings agree with the effects of these alleles in the B10 series (Table 2). (2) C3 levels of five congenic and congenic recombinant strains of the B10 series, which have identical alleles in the IC and S subregions (IC^d, S^d), were also compared. B10.A, B10.A(2R), B10.A(17R), B10.D2 and B10.A(5R) differ in the K, IA and IB subregions (*k*, *b*, *d* and *f* alleles) and also in the D subregion (*d*, *b* and *f* alleles). Their C3 levels, however (0.87±0.12, 0.89±0.11, 0.85±0.09, 0.86±0.08 and 0.83±0.12, respectively), were not significantly different ($F^4_{138} = 2.0$).

Table 2 C3 levels in congenic mice with different *H–2* haplotypes

Congenic line	*H–2*	C3 levels
C57BL/10sn	*b*	0.81
B10.D2	*d*	0.86
B10.M	*f*	0.95
B10.Br	*k*	0.96
B10.S	*s*	0.98

H–2^b against *H–2*^{d} ($F^1_{63} = 6.8$; $00.5 > P > 0.01$). *H–2*^{b}, *H–2*^{k} and *H–2*^{s} against *H–2*^{b} and *H–2*^{d} ($F^2_{140} = 40.6$; $P < 0.001$). The differences between *H–2*^{k}, *H–2*^{f} and *H–2*^{s} are not significant.

C3 levels in newborn mice are also influenced by gene(s) outside the *H–2* complex. Indeed, at 3 weeks of age significant differences ($P < 0.01$) were observed between C3 levels of mice with the same *H–2* but different backgrounds such as DBA/2J (0.54±0.06) and B10.D2 (0.86±0.08); B10.M (0.95±0.08) and A.CA (0.81±0.05); C3H.B10 (0.94±0.2) and C57BL/10 (0.81±0.09).

Because genetic polymorphism of human C3 can be detected by electrophoresis[9] we subjected the plasma of mice with *H–2*^{k}, *H–2*^{d}, *H–2*^{b}, *H–2*^{s} and *H–2*^{f} haplotypes in different backgrounds (A, C57BL, C3H, DBA/2J and AKR/J) to high voltage electrophoresis in Agarose gel. No differences in the mobility of the C3 band were observed. We conclude that the levels of C3 in newborn mice are controlled by at least two genes, one of which is situated in the central region of the *H–2* complex, as shown by segregation analysis and by the studies on congenic and congenic recombinant mice. In adult mice, significant differences in C3 levels were no longer detectable. Perhaps these genes cease to function, or more likely, their influence is masked by the activity of other genes and/or environmental influences.

The nature of the *H–2* gene which controls C3 levels in ontogeny is unresolved. On the basis of preliminary mapping, it can be separated from the *Hom–1* gene[10] situated at the K end of *H–2* (ref. 11) which influences testosterone levels and the relative weights of several organs which are hormone-regulated. Meruelo and Edidin[12] have demonstrated that basal levels o

cyclic AMP in the liver of adult mice segregate with *H–2* in F_2 mice, and also differ significantly among relevant combinations of congenic mice. They also present evidence to suggest that two genes, one at each end of the *H–2* complex, are involved. But the precise position of these genes within the subregions of *H–2* has not been determined. If one of the cyclic AMP genes is mapped within or close to the S subregion, the possibility of its direct or indirect involvement in the control of C levels should be considered.

Microtubule assembly mutant

WE report here a new maternal effect mutation (*nc*, for no cleavage) in the Mexican axolotl, *Ambystoma mexicanum*. This mutation involves a defect in the assembly of microtubules in the fertilised egg. There is a large literature describing the molecular and biochemical events which accompany the *in vitro* self-assembly of microtubules; the *nc* mutant is the first known system with a genetic lesion in the regulation of these events *in vivo*. This mutant will provide a means to examine directly the control of microtubule assembly, and may also be useful in the identification of the events which trigger initiation of cleavage after activation of the egg at fertilisation.

Eggs spawned by female axolotls homozygous for *nc* seem to be morphologically normal. They show normal interaction with sperm, which enter and cause activation of the eggs as determined by the standard criteria of cortical changes, formation of polar bodies and swelling and migration of the pronuclei. But no mitotic apparatus or cytasters are assembled and no cleavage occurs. The mutant eggs do contain a pool of soluble tubulin indistinguishable from that in normal eggs. (A detailed description of the characterisation of axolotl tubulin will be published elsewhere.)

We have found that the lesion in the *nc* mutant eggs can be partially corrected by injection of microtubule fragments. If fertilised *nc* eggs (which are arrested after the cortical activation stage) are injected with fragments of the outer-nine doublet tubules prepared from sea urchin sperm tail axonemes, they begin to cleave and proceed to partial blastula as shown in Fig. 1. Cleavage begins at about the time it would have started had the eggs initiated cleavage normally. Normal fertile axolotl eggs cleave about 7 h after spawning at 18 °C; fertilised *nc* eggs injected with doublet tubule fragments 1 or 2 h after spawning begin to cleave 5–6 h later. The initial cleavages are fairly normal in appearance in the animal hemisphere but there is little cleavage in the vegetal region of the eggs. Later cleavages become more irregular, resulting in the formation of partial blastulae, and the eggs finally arrest. The doublet microtubule fragments which elicit cleavage are composed of tubulin; dynein and other high molecular weight proteins are absent (Fig. 2).

No cleavage results after injection of soluble tubulin, buffer, non-tubulin particles or normal germinal vesicle nucleoplasm. In addition, no cleavage results after injection of doublet tubule fragments into activated *nc* eggs followed by bathing the eggs in colchicine at a concentration which arrests cell division of normal fertile axolotl eggs. Activation of the egg is necessary for the correction effect: injection of microtubule fragments into unactivated infertile eggs from either *nc* mutants or normal females does not cause cleavage.

In some preliminary experiments, eggs were injected with basal bodies isolated from *Chlamydomonas reinhardi*. These preparations are much more heterogeneous than the doublet tubule fragments and the results were more variable and difficult to assess. A very small proportion of eggs injected with basal bodies underwent cleavage comparable with that caused by doublet tubules; most did not cleave at all, and some underwent abnormal cleavage or fragmentation, which is clearly distinguishable from cleavage.

The *nc* mutant eggs can be phenocopied by electrically stimulating infertile eggs from normal females. This causes

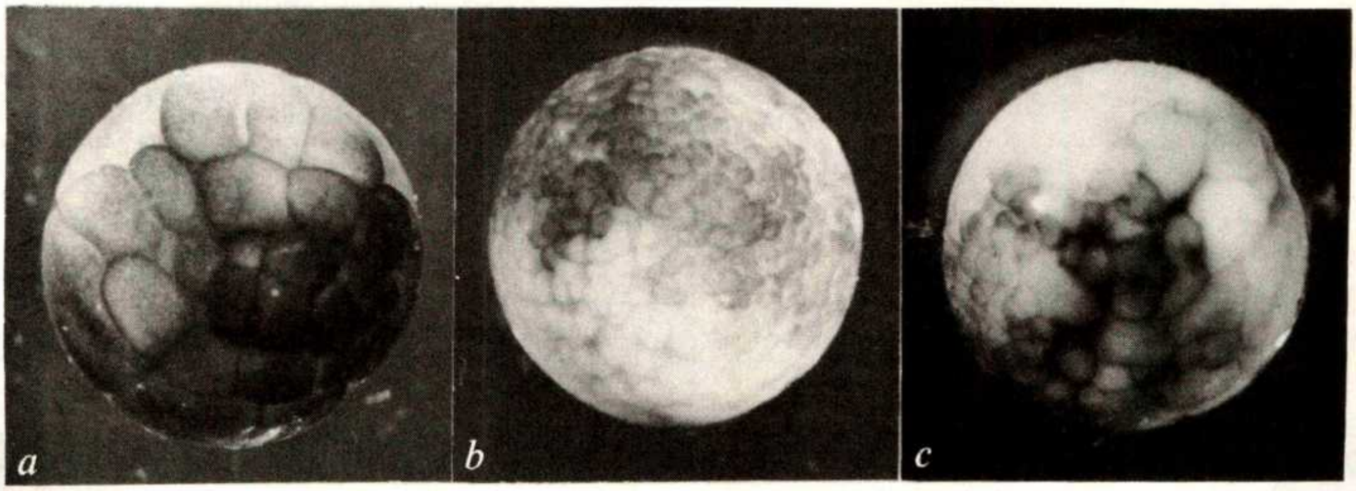

Fig. 1 Cleavage of normal and corrected *nc* mutant eggs. *a*, Normal fertilised egg in mid-cleavage. *b*, Mutant egg corrected by injection of doublet tubules. Cleavage has progressed in the animal hemisphere to form a partial blastula similar in appearance to a normal blastula. This is an example of the best correction observed. *c*, Mutant egg corrected by injection of doublet tubules. This is an example of the poorest correction observed containing patches of irregular sized cells.

Table 1 Induction of cleavage in *nc* mutant and normal axolotl eggs

Treatment	Mutant: activated *nc* eggs	Phenocopy: electrically activated normal eggs	Unactivated eggs: infertile *nc* or normal eggs
Injection of doublet tubule fragments prepared from sea urchin sperm tails	+*†	+	–
Injection of buffer	–*†	–	–
Injection of soluble tubulin prepared from *Drosophila* embryos	–*†	–	–
Injection of germinal vesicle nucleoplasm from normal eggs	–*	–	–
Injection of heat-killed bacteria (*Staphylococcus aureus*)	–*	–	–
Injection of doublet tubule fragments followed by bathing in 10^{-3} M colchicine‡ or 10^{-4} M vinblastine	–†	–	–

+, Initiation of cleavage; –, No cleavage.

* Activated by interaction with sperm (that is, fertilised eggs).

† Activated by electrical stimulation (of infertile eggs).

‡ This concentration of colchicine causes arrest of normally dividing fertile embryos. The relatively high concentration is necessary because of the impermeability of the eggs.

activation of the eggs so that morphologically they appear the same as fertilised eggs but they do not subsequently undergo cleavage. (Occasionally some of the electrically activated eggs fragment; these eggs are not used in correction experiments.) Electrically activated eggs also initiate cleavage to form partial blastulae when injected with doublet tubule fragments. Likewise, electrically activated infertile *nc* mutant eggs initiate cleavage when injected with doublet tubule fragments. A summary of the results of microinjection experiments is given in Table 1.

Preliminary light and electron microscopic observations of sections of the partial blastulae resulting from injected *nc* eggs show that the blastomeres are surrounded by complete cleavage furrows and that each blastomere contains an area in which the cytoplasm is cleared and in which parallel arrays of microtubules are formed. These arrays are occasionally but not usually organised into a shape resembling a true spindle. Chromosome fragments are found associated with these arrays in some (but not all) of the blastomeres. The initiation of cleavage thus appears to be due to a triggering of microtubule assembly from the existing pool in the egg, since the amount of tubulin contained in the injected fragments is less than 10% of the amount already present in the egg. In addition, in some cross sections we have observed doublet tubules, indicating that the injected fragments retain their morphological integrity.

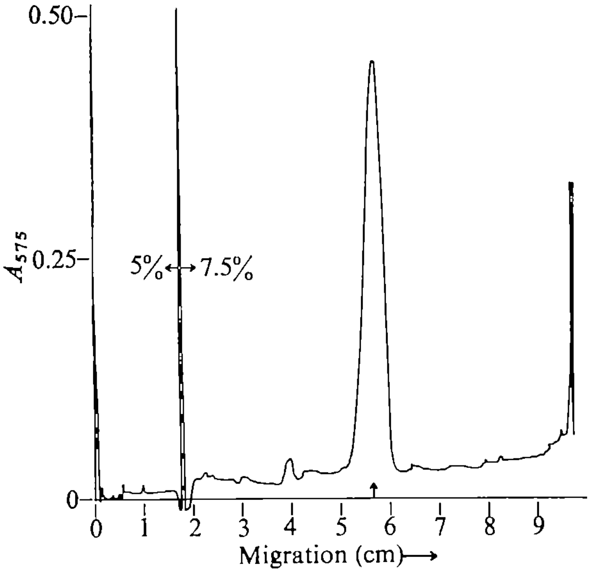

Fig. 2 Purity of injected doublet microtubule fragments. Doublet tubules were solubilised in 8 M urea–0.2% sodium dodecyl sulphate (SDS) buffer and electrophoresed on an SDS–urea polyacrylamide gel which was then stained with Coomassie blue and scanned. The running gel consisted of a 2-cm gel containing 5% acrylamide poured on top of an 8-cm gel containing 7.5% acrylamide. A stacking gel was poured over this. This allows good resolution of both high and low molecular weight sperm tail proteins. Tubulin (indicated by arrow) accounts for 97% of the protein present in the doublet tubule fragments used in our experiments. Dynein, which would be represented by a peak in the 5% gel, is absent from this preparation but is clearly visible in gels of whole axonemes.

It is our hypothesis that the lesion in the *nc* mutant lies in an early microtubule assembly event stimulated by activation, an event possibly analogous to the formation of mitotic organising centres in activated (but not in unactivated) eggs of the surf clam *Spisula*, as described by Weisenberg and Rosenfeld[1]. Although the correction obtained is not complete, in that the eggs do not finish embryonic development, nevertheless the normal timing of cleavage initiation and the presence of microtubule arrays and chromosome fragments in the blastomeres indicates that a process resembling normal cell division is elicited. One very intriguing aspect of the *nc* eggs is that during activation they seem to complete meiosis. We do not know whether this indicates a molecular difference in the meiotic and mitotic spindles or a difference in regulation.

Fraser achieved parthenogenetic development of *Rana pipiens* eggs by injection of crude fractions possibly containing microtubules[2]. Injection of axonemes from *Tetrahymena* or *Chlamydomonas* did not elicit cleavage; Heidemann and Kirschner[3] postulated that Fraser's active fractions contained centrioles. Ohta and Iwamatsu[4,5] achieved partial development of infertile eggs of the medaka by injecting them with flagella or microtubules prepared from sea urchin sperm. In both these organisms, unlike the axolotl, parthenogenetic development of infertile eggs is fairly readily induced and activation of the egg occurs during microinjection. Heidemann and Kirschner[3] demonstrated that injection of isolated basal bodies into infertile eggs of *Xenopus laevis* elicited both aster formation and initiation of a type of cleavage with irregular furrows and fragmentary blastomeres. This is similar to what we have scored in our experiments as fragmentation. These authors do not discuss the state of activation of the *Xenopus* eggs after injection of basal bodies. They found, however, that isolated flagella or axonemes were ineffective in inducing aster formation or cleavage when injected into infertile *Xenopus* eggs.

In the *nc* axolotl mutant there is a clear-cut separation between the events of activation and subsequent initiation of cell division. In this mutation, for the first time a genetic lesion has been found which involves the role of microtubule assembly in the initiation of cell division and subsequent embryonic development. A detailed description of this mutant will be published elsewhere.

Mechanical properties of vascular smooth muscle cells *in situ*

ALTHOUGH the histology and ultrastructure of smooth muscle cells have been studied extensively there is little direct evidence concerning their mechanical properties. Their small size[1,2] and lack of tendon connections have prevented them from being mounted on a myograph, as has been done with striated muscle fibres[3]. Moreover, their multiplicity and optical properties make it difficult to visualise them in whole smooth muscle preparations. Although isolated smooth muscle cells[4–6] can be seen to contract when stimulated, it has not been possible to measure the forces they develop. There are, therefore, still serious doubts about the extent to which the mechanical properties of whole smooth muscle preparations are an accurate reflection of the properties of smooth muscle cells. We have therefore developed a technique to obtain mechanical data from a smooth muscle preparation which only contains about 1,000 smooth muscle cells, and which is thin enough for the cells to be visualised by Nomarski interference microscopy[7]. This technique provides for the first time the means to study the mechanical properties of smooth muscle cells *in situ*.

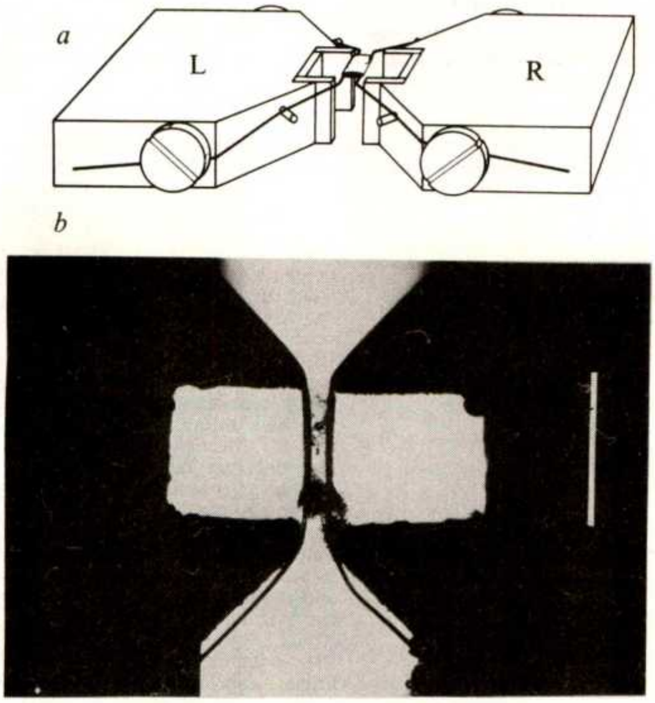

Fig. 1 *a*, Sketch showing method of mounting vessel segment. The vessels were excised from the animal together with about 1 cm of the proximal arterial tree. The latter was threaded on to a 32-μm tungsten wire and used to guide the wire into the lumen of the test vessel. The unwanted tissue was then dissected away and the wire was clamped at each end under tension to the left-hand support (L). A second wire was then passed through the lumen and similarly attached to the right-hand support (R). The supports were mounted respectively on a tension transducer (DSC 6, Kistler-Morse, resonant frequency 400 Hz with support mounted) and a piezoelectric vibrator (PZ40, Burleigh, range 19 μm, frequency response 0–2 kHz). The vibrator was in turn mounted on a micrometer translator for gross movement. Movement of R was detected using an eddy-current displacement transducer (KD 2300.5 SU Kaman). The supports were immersed in a chamber through which solutions were circulated. *b*, Low power micrograph of a vessel when mounted as described in (*a*) and viewed from above. The bar shows 1 mm.

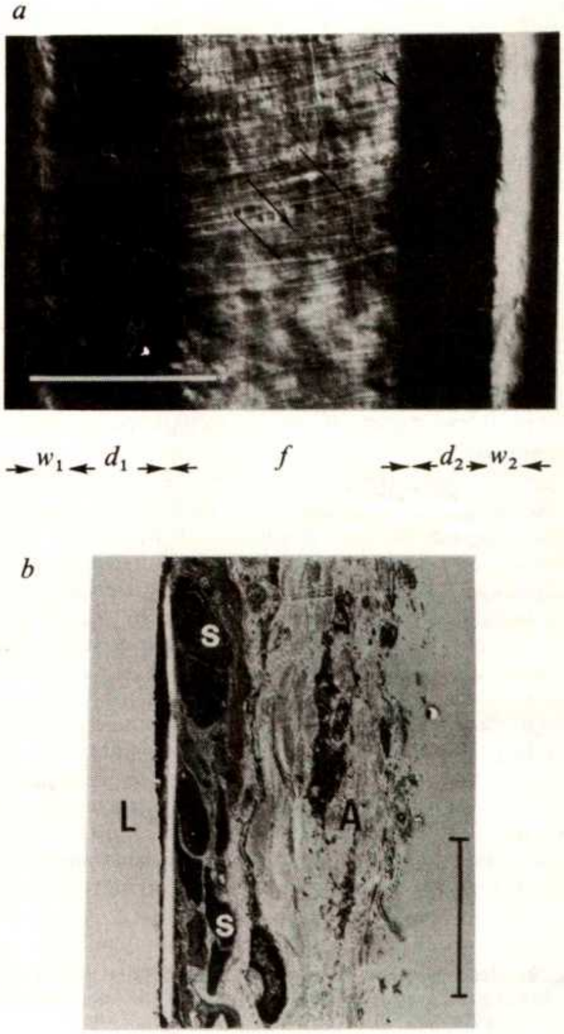

Fig. 2 *a*, High power micrograph of the vessel shown in Fig. 1*b* with focal plane in the media of the upper wall. The general outline of the smooth muscle cells is seen (the long arrows show a number of cell boundaries). The two dark areas (short arrows) are the 32-μm mounting wires. Photographed using Nomarski interference contrast optics[7] (Zeiss Universal) with ×40 water immersion objective. Condenser aperture fully opened to reduce depth of field to about 4 μm. The symbols indicate the dimensions which were measured using an ocular micrometer. The internal circumference, L, was calculated from the equation $L = (d_1+d_2)[1+(\pi/2)]+2f$. For this vessel $L_0 = 361$ μm and the segment length was 665 μm. The bar shows 50 μm. *b*, Electron micrograph of vessel shown in (*a*) sectioned radially to show the smooth muscle cells (S) and adventitia (A) in cross section. L indicates the lumen. The vessel was fixed at 36 °C at conclusion of the experiment after equilibration in relaxing solution. The vessel was prefixed on the myograph in 2.5% glutaraldehyde, 75 mM cacodylate, 4.5% sucrose, then removed from myograph and postfixed in OsO_4, 50 mM cacodylate, then blockstained in saturated aqueous uranyl acetate and embedded in Epon[19]. The bar shows 10 μm.

We used segments, about 0.7 mm long, of small (100 μm lumen) arterial resistance vessels. They were taken from the mesenteric bed of 5-month-old Wistar Kyoto rats from a point immediately proximal to the intestinal wall. Each vessel segment was threaded on to two wires attached respectively to a force transducer and a displacement device[8] (Fig. 1). This arrangement enabled the wall tension P and vessel internal circumference L to be controlled. The myograph was mounted on the stage of a microscope, enabling us to measure vessel dimensions (Fig. 2*a*). Oxygenated physiological salt solutions were circulated through the test chamber at 36 °C, *p*H 7.4. The vessels were maximally activated by K^+-depolarisation in the presence of 5 mM Ca^{2+} (ref. 9) and relaxed using the same solution with Ca^{2+} replaced by 1 mM EGTA. At other times the vessels were held in Ringer solution[10]. The overall myograph compliance was less than 0.5 $\mu m\ mN^{-1}$ and has not been corrected for. We report here results obtained from four typical experiments. The vessels were all held at an internal circumference, L_0, for which their active wall tension was a maximum P_0. Results are presented as mean ± s.e. The figures all refer to the data obtained from one of these vessels.

Figure 2*a* shows the appearance of the vessels in the light microscope in the conditions described in the legend. The general outline of the smooth muscle cells was clearly seen and the dimensions of individual cells were measured. The cells were spindle shaped, of length about 65 µm and diameter 4 µm, and were orientated approximately perpendicular to the wires. In some cells internal structures such as the nuclei and mitochondria could also be identified. When the vessels were activated, changes in the appearance of the cells were followed and although there was some rearrangement of the cells there was little change in their average length. The dynamic behaviour of the smooth muscle cells was then examined by monitoring the microscope image with a television camera and recording it on videotape. This was done during quick (5 ms) changes in internal circumference imposed by the displacement device while the vessels were activated. By replaying the tape one frame at a time, the frames immediately before and after the length change (which were separated by 17 ms) could be compared. Comparisons of the two frames showed that for length changes up to at least $10\% \cdot L_0$, the length of any smooth muscle cell was always a fixed proportion of the vessel internal circumference. In other words, changes in the strain of a vessel produced the same changes in the strain of cells. Thus active force–strain data obtained from these vessels were a measure of the active characteristics of the individual smooth muscle cells.

At the conclusion of the experiments the vessels were fixed on the myograph at L_0. Electron micrographs of longitudinal sections confirmed that the structures identified in Fig. 2*a* were indeed smooth muscle cells, and that their contractile material was generally well organised and orientated parallel to the long axis of the cells. Transverse sections (Fig. 2*b*) showed that the smooth muscle cells were closely packed in one to three layers, taking up 67% of the medial layer and 20% of the total wall.

Typical mechanical data obtained from the vessels are shown in Fig. 3. The total force developed by the vessels corresponded on the basis of the light and electron microscopy to an active wall stress of 72 ± 13 mN mm^{-2}, giving an active force per smooth muscle cell of about 5 µN and an active stress for the smooth muscle cells of 360 mN mm^{-2}. The last value can be compared with the figure of 370 mN mm^{-2} obtained for smooth muscle cells in hog carotid artery[10] and at least 300 mN mm^{-2} for frog striated fibres[11]. The dynamic stiffness was measured in two ways: from the step response of the vessel (Fig. 3*b*), and from the initial portion of the response of the vessels to a quick release sufficient to discharge the tension (Fig. 3*c*). These showed that the dynamic stiffness of small displacements was $67 \pm 6\ P_0/L_0$ and $81 \pm 16\ P_0/L_0$, respectively. The complete instantaneous elastic characteristic (Fig. 3*c*) was fitted approximately by an

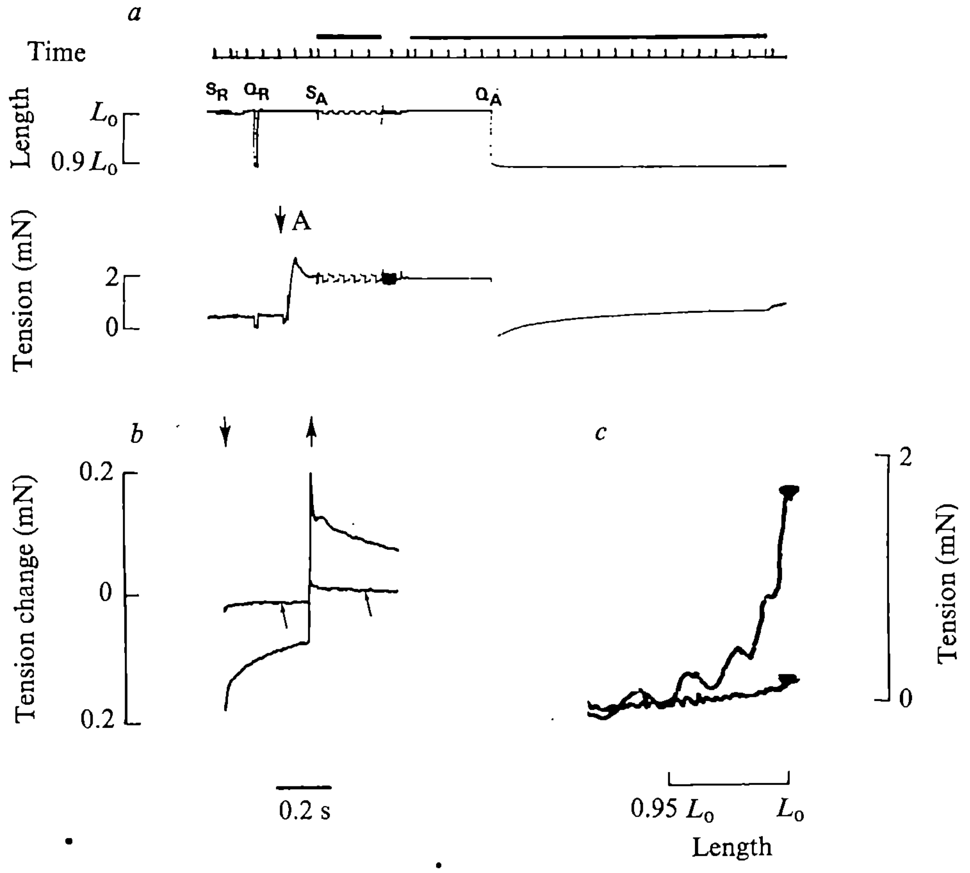

Fig. 3 Records of mechanical responses obtained from vessel shown in Figs. 1 and 2. *a*, Oscillograph record. The upper trace shows time; markers at 1-min or, under the bars (where the chart speed was increased), 1-s intervals. The centre trace shows length. The lower trace shows tension. The vessel was initially in relaxing solution (see text). At ↓A the solution was changed to activating solution. The response of the vessel to small (0.0028 L_0), repetitive (1.57 Hz) step changes in length was measured at S_R and S_A. The mean responses are shown in (*b*). The response of the vessel to quick releases (during 10 ms) through 0.086 L_0 was measured at Q_R and Q_A. The length–tension relationships during these releases are shown in (*c*). *b*, Mean of 32 tension responses to release (↓) and stretch (↑), obtained using signal averaging techniques sampling at 5-ms intervals, measured at the times indicated in (*a*) in relaxing solution (centre curves, arrowed) and in activating solution (outer curves). The active release and stretch responses, when expressed as unit step responses, $u_{-1}(t)$, are fitted approximately by the equations $u_{-1}(t) = -(P_0/L_0)(57.3-14.5 \log t)$ and $u_{-1}(t) = (P_0/L_0)(60.1-15.7 \log t)$, respectively. *c*, Oscilloscope plots of the length–tension relationship during the quick releases shown in (*a*) in relaxing solution (lower curve) and activating solution (upper curve). Vertical deflection represents tension and horizontal deflection represents length[20]. The difference between the active and relaxed responses is fitted by the equation $P = P_0 \exp[-77.6(\Delta L/L_0)]$. The oscillations on the upper curve are mechanical artefacts.

exponential equation as in hog carotid artery[12]. Analysis of the step responses (Fig. 3*b*) show that the rate constants of the tension decay and recovery (if defined as $(\mathrm{d}P/\mathrm{d}t)/(P_0-P)$) decreased throughout decay and recovery, but that their initial values were at least $0.038\pm0.005\ \mathrm{ms}^{-1}$. The corresponding figure for frog striated fibres at 0 °C is $0.4\ \mathrm{ms}^{-1}$ (ref. 13).

For the reasons discussed above, the data presented here represent the characteristics of smooth muscle cells *in situ* and, we believe, provide a basis for a better understanding of the relationship between structure and function in the smooth muscle cell. Structural studies[14,15] have shown that the contractile apparatus of smooth muscle cells is a sliding filament mechanism but that it is much less regularly organised than that of striated muscle. It is not known, however, how the contractile filaments transmit the force they generate to the extracellular environment. This contrasts with the situation for skeletal fibres, where it is clear that the contractile filaments are arranged in myofibrils which run the entire length of the fibre, being attached to the tendons at each end[16]. The dynamic stiffness of these fibres ($195\ P_0/L_0$) and their instantaneous elastic characteristic (IEC), which is approximately linear, are thought to be primarily the property of the crossbridges between the contractile filaments[17,18]. Our data for smooth muscle cells show them to have about half the dynamic stiffness of skeletal muscle fibres, while their IEC does not seem to be linear. This suggests that their dynamic compliance is divided between crossbridge compliance and a nonlinear compliance in intracellular supporting structures.

Previous mechanical studies on smooth muscle have used much larger preparations and the dynamic stiffnesses reported have been rather lower. The highest dynamic stiffness so far reported has been in hog carotid artery ($58\ P_0/L_0$)[12]. It seems likely that the differences between these results and ours may be due to a greater amount of connective tissue between the smooth muscle cells in the larger preparations. As we have shown above, in our preparation the effect of such intercellular compliance is minimal. We believe therefore that the preparation we have described may be useful in the detailed examination of the intrinsic mechanical properties of smooth muscle cells.

We thank Mr W. G. Boldosser for taking the electron micrographs and Mr Joseph P. Trono for constructing the myograph. The tungsten wire used for mounting the vessels was given by Westinghouse Corporation, Lamp Division. The work has been funded by the US National Institutes of Health.

M.J.M. is on leave-of-absence from the Biophysics Institute, Aarhus University, Aarhus, Denmark.

Note added in proof: We should like to draw attention to a recent report[21] of direct measurements of the force developed by isolated smooth muscle cells.

Calcium activation produces a characteristic response to stretch in both skeletal and cardiac muscle

RESTING frog skeletal muscle, when stretched at a constant velocity, exhibits a force response which, for length changes less than about 0.2%, is elastic in nature. First observed by Hill[1], this response was attributed to a short range elastic component (SREC) that was thought to be a property of a small number of cross bridges which, even in the resting state, extend from the myosin-containing thick filaments to interact with sites on the actin-containing thin filaments. This view was criticised[2] on the grounds that the SREC stiffness remained approximately constant as the amount of thick and thin filament overlap was decreased by increasing muscle length. On the basis of the sliding filament theory[3,4], SREC stiffness would be expected to decrease because reduced amounts of thick and thin filament overlap would result in a decreased number of cross bridges available in interact with thin filament sites. Flitney and Hirst[5] have reported that in twitch contractions of frog skeletal muscle a short range elastic response is present and is similar in form to that of resting muscle. In this case, however, a directly proportional relationship was found between the short range stiffness and the amount of overlap between the thick and thin filaments, which suggests that this stiffness is a property of attached cross bridges. To investigate the possible presence of attached cross bridges in resting muscle, we have measured the calcium dependence of the short range stiffness in skeletal and cardiac muscle preparations in which the myofibrils were directly exposed to the bathing medium.

Single muscle fibres were isolated from the semitendinosus muscle of the frog (*R. pipiens*) and their sarcolemmae were

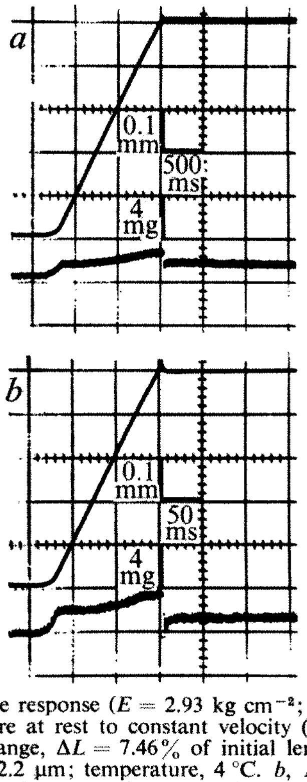

Fig. 1 *a*, Force response ($E = 2.93\ \mathrm{kg\ cm^{-2}}$; lower) of living frog skeletal fibre at rest to constant velocity (0.06 ML per s; total length change, $\Delta L = 7.46\%$ of initial length, L_i) stretch (upper). SL = 2.2 μm; temperature, 4 °C. *b*, As for *a* except velocity is 0.60 ML per s and $E = 5.70\ \mathrm{kg\ cm^{-2}}$. Responses are typical, demonstrating a steep initial rise which is the elastic part of the response, reaching an elastic limit at a change in length of about 0.3% and followed by Hill's[1] frictional phase as the stretch is continued. Short range elastic stiffness (expressed as modulus, E) is calculated as the height of the initial, fast part of the force response divided by the corresponding length change.

either removed by mechanical skinning[5] or made highly permeable by chemical treatment (that is, chemical skinning) with glycerine and a non-ionic detergent[6]. Thin longitudinal strips were cut from rabbit right ventricular papillary muscles and placed in glycerinating solution[6] at 0–5 °C for 3 d. Muscle segments, 1–3 mm long, were attached to wires extending from a force transducer and servo motor by means of glass jaws—two pieces of glass coverslip held flat together by slightly sprung strips cut from a stainless steel razor blade. This connection proved to be isometric, since no muscle movement with respect to the jaws was observed through the light microscope at ×400 magnification. Constant velocity length increases were applied at one end of the muscle preparation through an arm attached to the servo motor. Force was measured using a capacitance transducer with a sensitivity of 1 mV mg^{-1} and a natural resonance frequency of 800 Hz. All measurements were made at 4 °C. The solutions, apparatus and methods for controlling free Ca ion concentration using EGTA have been described[6]. Sarcomere length (SL) was measured and monitored continuously using a light microscope[6].

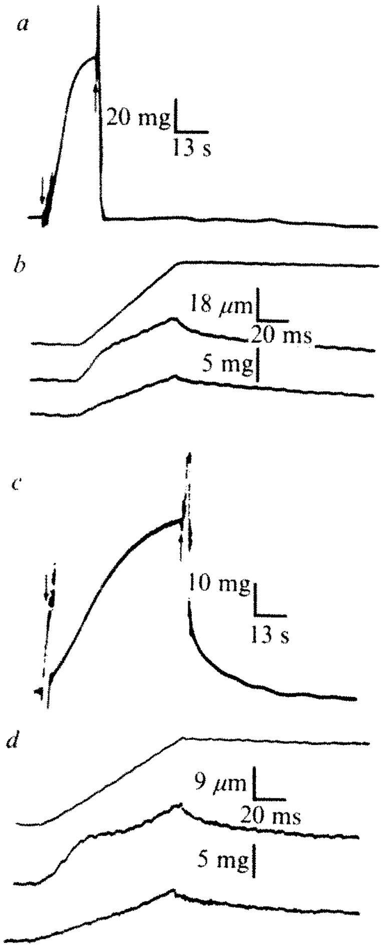

Fig. 2 *a*, Contraction time-course of glycerinated skeletal fibre when activating solution is applied (pCa = 5.76; first arrow) followed by relaxing solution (pCa about 9; second arrow). SL = 2.28 μm. *b*, Force responses of glycerinated skeletal fibre to constant velocity (0.34 ML per s; total ΔL = 1.90% L_i) stretch (upper) in relaxing solution (pCa about 9; E = 4.55 kg cm^{-2}; lower) and activating solution (pCa = 6.51; E = 15.3 kg cm^{-2}; middle). SL = 2.28 μm. *c*, Contraction time course of glycerinated papillary muscle strip when activating solution is applied (pCa = 5.76; first arrow) followed by relaxing solution (pCa about 9; second arrow). SL = 2.14 μm. The slower time course relative to that of the skeletal fibres is typical of the heart preparations used. *d*, Force responses of glycerinated papillary muscle strip to constant velocity (0.46 ML per s; total ΔL = 3.66% L_i) stretch (upper) in relaxing solution (pCa about 9; E = 2.25 kg cm^{-2}; lower) and activating solution (pCa = 6.51; E = 6.75 kg cm^{-2}; middle). SL = 2.14 μm.

The calcium sensitivity of the three preparations was quantified to establish a basis for comparison of the stiffness measurements which follow. In each case, the calcium threshold for active tension development was near a pCa (negative log of free Ca ion concentration) of 6.9. At higher calcium ion concentrations the typical S-shaped relationship between tension and pCa was confirmed[6]; in all cases no further increases in active tension development were noted at pCa less than 6.

Short range elastic stiffness was measured first on living, resting single frog skeletal muscle fibres (Fig. 1). At a velocity of stretch of 0.06 muscle lengths (ML) per second, an elastic modulus (E) of 2.93 kg cm^{-2} was measured, comparing well with the value of 2.23 kg cm^{-2} found by Lannergren[7] using a slower rate of stretch (about 0.005 ML per s) and a similar preparation. In accordance with the findings of Hill[1], we found that the measured value of E rose as a function of increasing velocity of stretch, an effect especially prominent at velocities greater than 0.004 ML per s. A stretch rate of around 0.40 ML per s was chosen for use in the stiffness measurements involving the chemically activated preparations in order to take advantage of the enhancement of the response at higher stretch velocities.

Constant velocity stretches were applied to the mechanically and chemically skinned muscle preparation (Fig. 2) while in relaxing solution, in which there is no added cal-caffeine. The nearly exact similarity of the tension responses of the type reported by Hill for living muscle, and shown in Fig. 1, was found. Instead, tension increased steadily with increasing length to a level characteristic of the final length, there being some slight stress-relaxation when movement stopped. The form of the response changed considerably, to that typical of living muscle, when solutions containing small amounts of added calcium were applied. The threshold for this transformation was about pCa 7. At pCa less than 7, the measured short range stiffness increased sharply with decreasing pCa. No stiffness measurements were made, however, at pCa less than 6.09, because marked decreases in active tension development during subsequent contractions were observed after stretches at these pCa levels.

We investigated the possibility that the sarcoplasmic reticulum (SR) has a role in determining the tension response of muscle to constant velocity stretch. Caffeine (10 mM) in the presence of 0.1 mM EGTA was applied to each preparation after successive treatments with a normal activating solution (pCa 6.7) and relaxing solution containing low EGTA (0.1 mM), a procedure similar to that described by Endo[8]. Only the mechanically skinned skeletal fibres showed a functionally intact SR, as judged by a large tension response of transient duration after application of caffeine. The nearly exact similarity of the tension responses to stretch in the mechanically and chemically skinned fibres indicates that the SR does not have a major influence in the determination of short range stiffness.

These results show that the short range stiffness of resting muscle depends on the concentration of calcium in the fluid bathing the myofibrils. Calcium is believed to trigger the interaction of cross bridges with sites on the thin filaments by binding with the regulatory protein troponin which is located at intervals along the thin filaments[9]. Also, X-ray diffraction data suggest that in skeletal muscle activation may affect cross-bridge configuration causing the cross bridges to move out from the thick filaments and toward the thin filaments[10]. Other X-ray work[11] indicates that in living, isolated heart muscle a few cross bridges may be in an activated, though not necessarily attached, position while the muscle is at rest. Therefore, the short range stiffness seems to be a property of calcium-activated cross bridges which have either become attached to thin filament sites or at least changed from a resting to an activated position. To this extent, our work confirms Hill's hypothesis[1] that cross bridges are the source of the SREC.

The finding that the short range elastic response is virtually absent in muscles bathed in relaxing solution but is present at *p*Ca near 7 implies that the calcium concentration in the myoplasm of living fibres at rest is about *p*Ca 7. Finally, the short range elasticity has for the first time been shown to be present in a heart muscle preparation. The discovery of this elastic response as a characteristic of both heart and skeletal muscles suggests that the calcium mechanism which underlies the response is the same in the two cases.

Ultrastructural identification of granules containing oxytocin and vasopressin

OXYTOCIN and vasopressin, the hormones of the mammalian hypothalamo–neurohypophysial complex, are synthesised in the supraoptic (SON) and paraventricular (PVN) nuclei and are secreted into the blood stream from the neurohypophysis. It is now thought that the two hormones are produced in both nuclei, but are stored, together with their corresponding neurophysins, in distinct neurosecretory granules located in separate perikarya and axons, on the basis of data from various species including fish, reptiles, birds and mammals[1–4]. This study describes cytochemical experiments carried out on tissue from normal rats and from rats homozygous for hereditary diabetes insipidus (Brattleboro strain) that support this view and allow a tentative identification of the two granule types.

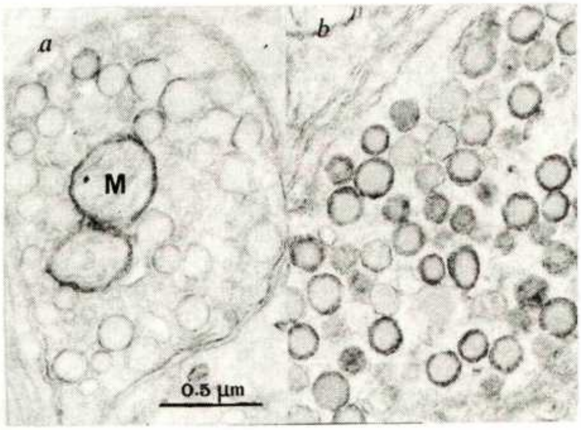

Fig. 1 Secretory axons in the neurohypophysis of normal rats. Potassium ferrocyanide–OsO_4 method. *a*, A neurosecretory axon with non-reactive granules. *b*, An axon in which the granules have the ring-shaped electron-dense deposit around their core. M = mitochondria.

Three methods believed to detect glycoproteins at the ultrastructural level were used: the periodic acid–thiocarbohydrazide–silver proteinate technique[5], the periodic acid–chromic acid–silver methenamine technique[6] and the potassium ferrocyanide–osmium technique[7]. Following each reaction, two distinct types of neurosecretory axon were recognised within the neural lobes of normal rats (Sprague–Dawley strain)[8,9]. In one type of axon, most granules had a ring-shaped silver or ferrocyanide–osmium deposit around their core. In the other type of axon, all granules had an homogeneous content of low electron density (Fig. 1). This contrasting aspect could be enhanced further by combining uranyl acetate impregnation *en bloc* with a subsequent proteinate silver reaction on ultrathin sections. Figure 2 shows the characteristic, positive reaction of the granules in one axon from a neural lobe treated with uranyl acetate *en bloc*. Variations in the plane of section may account for the unequal intensity of the reaction in granules of the positive axon. A small number of unreactive granules were sometimes seen intermingled among reactive granules, but they usually had an electron-lucent space between the membrane and core which was absent in the granules seen in non-reactive axons. Of 3,400 axons in normal Sprague–Dawley neurohypophyses, 68% were found to be positive. Axons of each type frequently occurred in small groups.

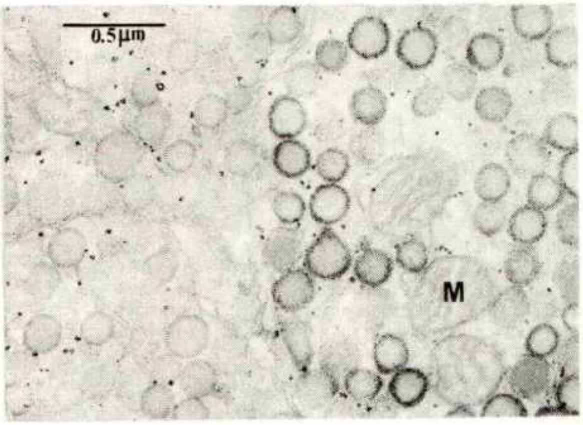

Fig. 2 Secretory axons in the neural lobe of a normal rat. Uranyl acetate and periodic acid–thiocarbohydrazide–silver proteinate method. Note presence of axons containing non-reactive granules (left), and reactive granules in another, adjacent axon (right).

The same methods revealed a similar duality in the hypothalamic magnocellular nuclei. This was particularly obvious in PVN, where perikarya and axons contained either reactive granules or non-reactive ones. In SON, the non-reactive type seemed to be less frequent, at least in the portion lateral to the optic chiasma, the region usually investigated for technical convenience.

These results indicate, therefore, that a distinction can be made between two types of neurosecretory axons and perikarya in normal rats. Since homozygous Brattleboro rats are characterised by an absolute deficiency in vasopressin (and vasopressin–neurophysin) biosynthesis[10,11], the same methods were applied to 19 of these animals to identify those axons and perikarya containing oxytocin granules. Before fixation, 9 animals were treated for 1 month with exogenous vasopressin (Pitressin tannate, Parke–Davis, 1 IU d^{-1} subcutaneously)[12]. We found that granulated axons were more frequent in the neurohypophysis of treated rats. They generally occurred in clusters surrounded by areas devoid of neurosecretory granules. All the granules observed in the neural lobes of homozygous Brattleboro rats were non-reactive (Fig. 3*a*). There was some deposit of silver proteinate on the granule-limiting membranes, in particular following treatment with uranyl

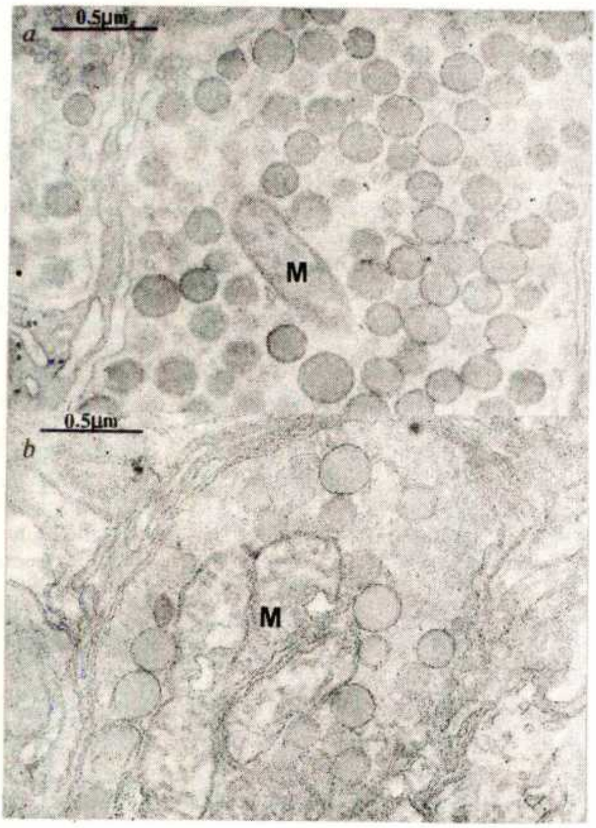

Fig. 3 Micrographs from homozygous Brattleboro rats treated with Pitressin tannate. Periodic acid–thiocarbohydrazide–silver proteinate method. Note that in the neurohypophysis (*a*) and in the hypothalamic paraventricular area (*b*) secretory axons contain only axons of the non-reactive type.

acetate *en bloc*, but the granule cores appeared homogeneous and did not show the characteristic annulate density. As in normal rats, we also studied the PVN and that part of the SON which is adjacent to the optic chiasma. The granules found in the axons and perikarya of these nuclei in homozygous Brattleboro rats were also non-reactive (Fig. 3*b*). Normal rats of the same strain (Long–Evans) served as controls. Of 1,600 neurohypophysial axons examined, 34% contained the reactive granules.

In view of the absence of reactive granules in homozygous Brattleboro rats, we propose that the reactivity of the neurosecretory material to the histochemical 'stains' used in this study is associated with the vasopressin-containing granules. Oxytocin is thus stored in the non-reactive granules. We do not at present know what accounts for the reactivity of the vasopressin granules, but their difference from the oxytocin granules may be in glycoprotein composition. Our results also support the idea that vasopressin and oxytocin are present in distinct neurones found in both PVN and SON.

We thank Mrs S. Rua for technical assistance, the Institut für medizinischbiologische Forschung, Fillensdorf, for supplying the Brattleboro rats, and the CNRS and INSERM for support.

Primary structure of human β-lipotropin

AFTER the discovery and isolation of β-lipotropin from sheep pituitary glands[1,2], the hormone has also been obtained in highly purified form from bovine[3], porcine[4–6], and human[7,8] pituitaries. The complete amino acid sequences of ovine[9,10] and porcine[11–13] hormones have been proposed. To gain insight into the evolutionary history of lipotropins and their structure–function relationships, and in view of recent data on the opiate agonist activity of peptide fragments from β-lipotropin[14,15], we report here the complete amino acid sequence of the human hormone.

Highly purified β-lipotropin (β_h-LPH) was obtained from fresh-frozen human glands by the procedure previously described[9] for the ovine hormone with minor modifications. It behaved as a single component in disc electrophoresis and partition chromatography experiments. Sedimentation equilibrium data gave a molecular weight of 11,700. Amino acid analysis, performed in the automatic amino acid analyser by the procedure of Moore[16] gave the following empirical formula (91 amino acid residues): Trp (1) Lys (9) His (2) Arg (5) Asp (10) Thr (4) Ser (4) Glu (11) Pro (6) Gly (11) Ala (8) Val (2) Met (2) Ile (2) Leu (8) Tyr (3) Phe (3). The NH_2-terminal sequence as determined by the dansyl–Edman procedure[17,18] was found to be: Glx–Leu–Thr–Gly–Glx–Arg–Leu–Arg–.

For the primary structure determination, a tryptic digest of β_h-LPH (3 mg) was fractionated by the two-dimensional paper chromatography–electrophoresis as described previously[19]. The eluates from each spot were submitted to amino acid[16] and sequence[17,18] analyses. Amino acid contents of the twelve tryptic peptides account for the composition of the hormone. All tryptic peptides have been completely sequenced except T12 which has 31 amino acids with the following composition: Lys (1) His (1) Asp (6) Ser (1) Glu (4) Pro (2) Gly (5) Ala (6) Val (1) Leu (4).

In order to obtain the sequence of T12, it was necessary to isolate the peptide by submitting the tryptic digest of β_h-LPH (17 mg) on Sephadex G-25 (fine) in 0.1 M HOAc. The material in the second peak was recovered by lyophilisation and shown to be peptide T12 with a yield of 3.3 mg. Two samples of T12 (1 mg) were digested separately by pepsin and thermolysin; the digests were mapped and eluates of each spot were subjected to amino acid and sequence analyses. For the determinations of Asp/Asn and Glu/Gln, amino acid analysis of the leucineaminopeptidase and electrophoretic mobility of *p*H 6.7 on paper were used.

The following chymotryptic peptides (see Fig. 1) were obtained by two dimensional chromatography-electrophoresis of the chymotryptic digest (1 mg) in order to align the tryptic peptides: C17B, C8, C18, C23, C4, C16, C5, C15, and C2. These chymotryptic peptides were analysed for amino acid composition and partially sequenced. From these data, the complete amino acid sequence of β_h-LPH is proposed as shown in Fig. 1.

Fig. 1 Amino acid sequence of human β-lipotropin.

has been reported by Cseh *et al.*[20]. In addition, these investigators indicated that their β_h-LPH preparation has the NH_2-terminal sequence: NH_2–Glx–Gly–Asx–. Our data, shown in Fig. 1, are in agreement with the Hungarian workers on the COOH-terminal sequence but differed on the sequence at the NH_2-terminus.

From a comparison of the proposed structure of β_h-LPH with the lipotropin sequences of other species[9–12], it is evident that the sequence of COOH-terminal 56 residues is surprisingly homologous whereas the amino acid sequence at the NH_2-terminus exhibits considerable variability as shown in Fig. 2.

Cross tolerance between morphine and methionine-enkephalin

TOLERANCE and dependence are characteristic symptoms in man during prolonged use of opiates. We have pointed out[1] that for an understanding of these phenomena the interaction between endogenous enkephalin and exogenous opiates is of importance. Normally, enkephalin can be assumed to control inhibitory mechanisms determining the rate of neurotransmitter release. If, however, opiates are administered with the intent of increasing the effects of these inhibitory mechanisms, then control will pass from the endogenous enkephalin to the exogenous opiates. Since tachyphylaxis is a pharmacological characteristic of opiates, a state of tolerance will arise in which increasing amounts of opiates will be required to maintain the desired effect. As an important step in the elucidation of the mechanism of action of enkephalin, it was necessary to establish whether cross tolerance between enkephalin and opiates is found in morphine-tolerant animals. This point was tested in two morphine-sensitive models, the myenteric plexus–longitudinal muscle preparation from the guinea pig ileum[2,3] and the mouse vas deferens[4]. As natural enkephalin consists of about 75% methionine–enkephalin and 25% leucine–enkephalin[5], the relative potencies of synthetic methionine–enkephalin and morphine were compared in preparations obtained from animals with different degrees of tolerance. Cross tolerance between morphine and methionine–enkephalin was shown to occur in the two preparations obtained from animals implanted with morphine pellets.

Mice were implanted with 1 or 2 pellets, each containing 75 mg morphine base, and guinea pigs with 2 or 4 pellets. After 3 d the animals were killed; the myenteric plexus longitudinal muscle[2] was prepared for isometric recording or the vas deferens[4] for isotonic recording. The bathing medium contained either no morphine or, to imitate the *in vivo* conditions, 0.5, 1 or 2 μM morphine. After approximately 2 h of exposure, the morphine was washed out and, when the sensitivity to morphine or methionine–enkephalin stopped increasing, dose–response curves for morphine and methionine–enkephalin were obtained and the ID_{50} values calculated. Preincubation with morphine had no consistent effect on the ID_{50} values.

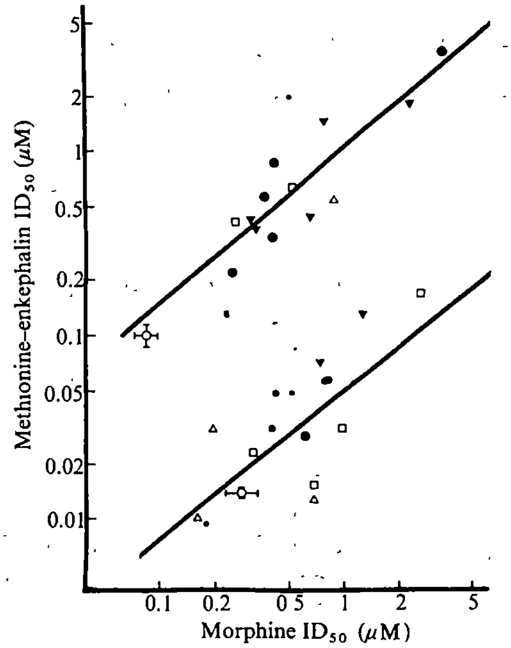

Fig. 1 Correlation between ID_{50} values of morphine and methionine–enkephalin. Myenteric plexus–longitudinal muscle preparation of the guinea pig ileum (upper line) and mouse vas deferens (lower line) from controls and animals implanted with pellets of morphine base. Controls, ○; implanted animals, tissues not preincubated with morphine, □; implanted animals, tissues preincubated with morphine, △ 0.5 μM, ▼ 1 μM, ● 2 μM. The lines were drawn from calculated regressions, the slope of the upper line being $b = 0.84$ and that of the lower line $b = 0.79$.

The results (Fig. 1) show that in both preparations tolerance of varying degree had developed. In the ileum from control guinea pigs the ID_{50} of morphine was 94.4 ± 13.2 nM and that of methionine–enkephalin 114.7 ± 19.7 nM, with a potency ratio of enkephalin to morphine of 0.89 ± 0.08 ($n = 12$). In the preparations from pellet-implanted guinea pigs, the ID_{50} values were increased 3 to 400-fold but the mean potency ratio of 0.97 ± 0.10 ($n = 13$) did not differ from that found in the controls. Similar results were obtained for the mouse vas deferens, although the correlation was not as good as in the myenteric plexus and there was an overlap of the ID_{50} values of preparations from pellet-implanted and non-implanted mice. The potency ratio of enkephalin to morphine was 21.5 ± 4.6 ($n = 4$) in the controls and 22.9 ± 5.3 ($n = 10$) in preparations from pellet-implanted mice.

The molecular mechanisms underlying cross tolerance are uncertain. Since the number of receptor sites in brain or their affinity to opiates are the same in normal and morphine-tolerant rats[6], tolerance and, therefore, also cross tolerance may be due to a process subsequent to the activation of the recognition sites of the receptor complex. This possibility is supported by the observation that the myenteric plexus–longitudinal muscle preparation obtained from morphine-tolerant guinea pigs shows reduced sensitivity to the depressant effects not only of morphine but also of adrenaline and noradrenaline[7,8]. The importance of this observation lies in the fact that the depressant effect of catecholamines is due to activation of presynaptic α-adrenoceptors[9] which are different and separate from opiate receptors[10]. It is possible that changes in adenylate cyclase activity[11,12] represent the common factor in the simultaneous changes in the sensitivity to opiates and catecholamines.

Analgesia induced *in vivo* by central administration of enkephalin in rat

ENKEPHALIN, a natural opiate receptor agonist in brain[1–4], has been identified by Hughes *et al.*[5] as a mixture of two pentapeptides: H–Tyr–Gly–Gly–Phe–Met–OH (methionine–enkephalin) and H–Tyr–Gly–Gly–Phe–Leu–OH (leucine–enkephalin). Both peptides mimic the ability of morphine to block electrically evoked contractions of mouse vas deferens and guinea pig ileum, and both inhibit the stereospecific receptor binding of the opiate antagonist ^{3}H-naloxone in brain homogenates[5]. On the basis of this and other[6–8] evidence, it has been proposed[2,9,10] that enkephalin receptors may be sites at which morphine-like drugs exert their analgesic actions, and that the enkephalins themselves may be modulators or transmitters in brain systems for pain suppression or analgesia. Consistently with this suggestion, we find that methionine–enkephalin and leucine–enkephalin, when administered through permanently indwelling cannulae in the lateral ventricles of rats, induce a profound analgesia *in vivo* that is fully reversible by naloxone.

Methionine–enkephalin and leucine–enkephalin were synthesised by the solid phase method. After purification by gel filtration, homogeneity of the peptides was verified by amino acid analysis and thin-layer chromatography. Intraventricular cannulae, constructed from 27-gauge stainless steel tubing, were implanted in 300–400-g male Charles River rats under pentobarbital anaesthesia, as described previously[11]. After a recovery period of at least one week, the rats were tested in the tail-flick procedure of D'Amour and Smith[12], an analgesic test with good selectivity for opiate drugs[13]. Animals were comfortably restrained in a wire-mesh cylindrical chamber so that the tip of the tail could be positioned at the focal point of a radiant heat source (1183 GE lamp). After an acclimatisation period of 15 min, the lamp was turned on and an electric clock was activated. Movement of the tip of the tail exposed a photocell to the lamp, which turned off the thermal stimulus and stopped the clock. If the rat failed to move its tail within 8 s, the heat was automatically turned off to prevent blistering. The intensity of the lamp was adjusted in each case to produce at least three baseline tail-flick latencies of 2.5–5 s. Tests were made every 2 min.

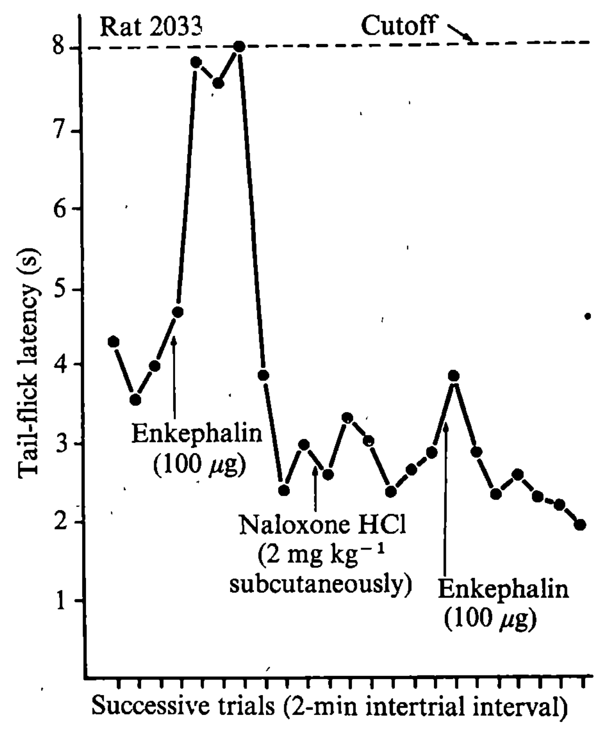

Fig. 1 Analgesic effect of intraventricularly-administered methionine–enkephalin and its prevention by subcutaneous administration of naloxone in a representative rat. Note especially the brief delay in onset of the first enkephalin response, and the apparent absence of effect on response latency of naloxone itself.

After preliminary experiments to establish the effective dose range, 100 or 200 μg of methionine–enkephalin or leucine–enkephalin was dissolved in 10 μl of Ringer's solution and injected in the lateral ventricle at a rate of 0.2 μl s^{-1}. Injections of Ringer's solution at *p*H 4.0 (to approximate the *p*H of the enkephalin solutions) served as control. To minimise disturbance of the rats, connections to the intraventricular cannula were made before the baseline tests. Behavioural reactions to the injection itself were rarely observed.

Statistically significant increases in tail-flick latency

Table 1 Analgesic activity of enkephalin and morphine as assessed by an increase in the latency of a tail-flick response to noxious thermal stimulation in different groups of rats

Drug	Dose (μg)	No. of rats	Mean latency±s.e.m. Baseline	Mean latency±s.e.m. Drug	Mean % change±s.e.m.
Ringer's (*p*H 7.4)		10	3.73±0.27	3.94±0.25	7.4±6.2
Ringer's (*p*H 4.0)		13	4.02±0.20	4.27±0.28	6.6±6.9
Morphine sulphate	10	7	3.96±0.42	6.59±0.73†	65.4±9.1
Methionine–enkephalin	100	24	3.83±0.14	5.19±0.31†	37.2±8.8
	200	3	2.88±0.41	4.99±0.85*	77.8±35.8
Leucine–enkephalin	100	11	3.97±0.17	5.11±0.34*	31.7±11.5
	200	4	3.35±0.35	5.54±0.72†	70.5±29.3

*Drug minus baseline significantly different from Ringer's (*p*H 4.0) minus baseline, $P < 0.05$.
†$P < 0.01$.
All drugs were dissolved in 10 μl of Ringer's solution and injected in the lateral ventricle through permanently-indwelling cannulae. Numbers give mean latencies of three "baseline" and five "drug" responses recorded consecutively at 2-min intervals just before and after injections.

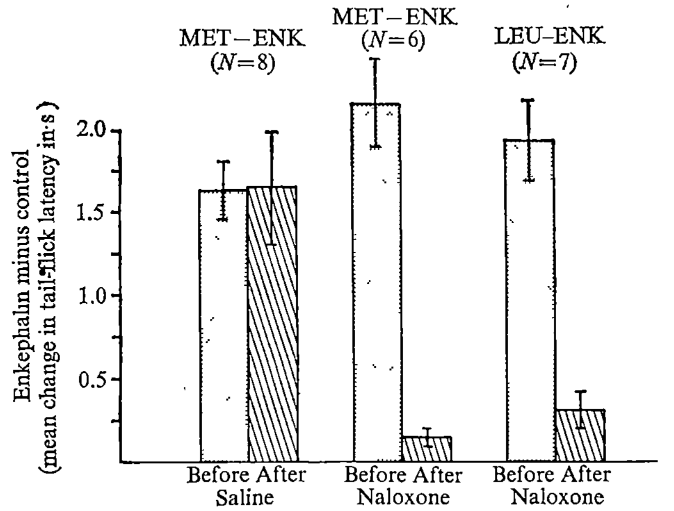

Fig. 2 Summary data of naloxone-reversal experiments. Methionine-enkephalin (MET–ENK) or leucine–enkephalin (LEU–ENK), in intraventricular doses of 100 or 200 μg, was administered both before (stippled) and 12–16 min after (hatched) subcutaneous injections of 2 mg kg^{-1} of naloxone (or saline). Analgesic responses to both peptides were significantly ($P < 0.025$) reduced following naloxone. Bars indicate standard errors.

followed injections of both peptides (Table 1); in most cases, the 8-s cutoff was reached at the peak of the drug action. The analgesic effect developed rapidly after a definite latent period (2–6 min) and dissipated rapidly (10–12 min) (Fig. 1). Although systematic dose–effect data were not obtained, the larger dose of both substances produced a stronger effect. Methionine–enkephalin and leucine–enkephalin were similar in potency, but each was less potent than morphine by an order of magnitude or more. The analgesia caused by intraventricular administration of 10 μg of morphine sulphate matched in intensity and reliability that induced by 200 μg of the enkephalins, although the effects of morphine lasted substantially longer (>1 h). The weaker potency and shorter duration of action of the natural substances may be attributed at least in part to their relatively rapid degradation by brain enzymes[2]. Slow permeation of the peptides to deeply situated receptor sites, as suggested by the delay in onset of action, would further favour their inactivation.

Blockade of the analgesic response by naloxone was evaluated in 13 rats that had exhibited a reliable effect to either methionine–enkephalin or leucine–enkephalin. After the effects of the first dose of enkephalin had clearly worn off, 2 mg kg^{-1} of the opiate antagonist was administered subcutaneously. 12–16 min later, at the approximate peak of the action of naloxone, the enkephalin dosing was repeated. In all naloxone-treated rats, the analgesic response to the second injection of peptide was virtually abolished (Fig. 2). In control experiments, subcutaneous administration of saline in place of naloxone was shown to have no measurable effect on the response to methionine–enkephalin.

Our observations suggest that enkephalin has opiate-like analgesic properties. In pharmacological studies of pain perception, however, especially when a substance is injected directly in the brain, serious consideration must be given to the possibility of artefacts. This possibility seems remote in the present case for several reasons. First, the detailed pattern of analgesic activity after systemic administration of morphine is reproduced by microinjections of the drug into the ventricles or central grey matter of the brain[7,8,14]. Second, as already indicated, the D'Amour–Smith test is highly selective for opiate-like activity and tends to yield negative results for other drugs, even non-opiate analgesics. Finally, naloxone blockade may be taken as a specific indication that enkephalin induces analgesia by activation of opiate receptors. We therefore conclude that our findings lend support to the concepts of Hughes[2] and Liebeskind et al.[7] that enkephalin may serve as a natural opiate-like neurohormone in a central mechanism for the inhibition of pain.

Inability of bats to synthesise L-ascorbic acid

RECENT speculations on the loss and retention of the ability to synthesise L-ascorbic acid (vitamin C) during evolution of animals have been based on few data, often for limited numbers of species[1]. Published reports for the Mammalia deal mostly with domesticated and laboratory species, and there is little information on ascorbate biosynthesis in wild populations. The status of knowledge on bats typifies this paucity of data. It has been reported that two species of bats (of approximately 850 species), like anthropoid primates and guinea pigs, are unable to synthesise vitamin C because they lack L-gulonolactone oxidase[2]. When present, this enzyme catalyses the final step in the biosynthesis of L-ascorbic acid from glucose. These species are *Pteropus medius*[3] (=*P. giganteus*), a fructivore of the suborder Megachiroptera, and *Vesperugo abramus*[2,4] (presumably *Pipistrellus coromandra*), an insectivore of the only other chiropteran suborder, the Microchiroptera. We have assayed livers of 34 species of New World microchiropteran bats for L-gulonolactone oxidase (Table 1). These species represent six families, temperate and tropical environments, and a wide variety of food habits and life histories. Within the limits of our assay, we could not detect L-gulonolactone oxidase in livers of any of the species examined. This greatly strengthens the hypothesis that all members of the Chiroptera lack the ability to synthesise vitamin C, which is surprising considering the diversity of bats and their many highly specialised diets.

L-Gulonolactone oxidase has been detected in the microsomal fraction of liver cells[5] in all mammals shown to synthesise ascorbate. Most previously reported investigations involved a technique in which microsomes are prepared from liver homogenate by differential centrifugation, and only the microsomal fraction is analysed for the enzyme[5]. We have shown, however, that a large portion of the enzyme may remain with other fractions and thus not be recovered with the microsomes[6]. Enzyme activities for *Pteropus* and *Vesperugo* were reported[3,4] as "nil".

The Centre for radiochemicals

Circle No. 08 on Reader Enquiry Form.

Although these workers probably used a quantity of microsomal preparation equivalent to 0.25 g of liver in the assay, the sensitivity of their method cannot be assessed adequately because of the potential for loss of any existing L-gulonolactone oxidase during preparation of the microsomes.

A more sensitive method[6], in which essentially all the L-gulonolactone oxidase is solubilised by homogenising liver tissue in a medium containing sodium deoxycholate, was used for the assays reported here. This method detects lower levels of L-gulonolactone oxidase in liver than does the microsomal method. When assays are conducted on individuals the techinique may be limited by the small size

Table 1 Bats examined for L-gulonolactone oxidase in the liver

Species examined	No. and sex of specimens ♂♂	♀♀	Specimen origin*	L-Gulonolactone oxidase activity†
Family Noctilionidae				
Noctilio leporinus	2		Tropics	< (0.06–0.07)
Family Mormoopidae				
Pteronotus davyi	2		Yucatan	< 0.07
Pteronotus parnelli	2	3	Tropics	< 0.09 (0.07–0.11)
Pteronotus suapurensis	1		Costa Rica	0.18
Mormoops megalophylla	1		Yucatan	< 0.08
Family Phyllostomatidae				
Subfamily Phyllostomatinae				
Micronycteris megalotis	1		Yucatan	< 0.09
Mimon cozumelae	1		Yucatan	< 0.09
Subfamily Glossophaginae				
Glossophaga soricina	9		Tropics	< 0.20 (0.07–0.30)
Glossophaga soricina		9	Costa Rica	< 0.18 (0.08–0.30)
Subfamily Carollinae				
Carollia brevicauda	3		Tropics	< 0.11 (0.08–0.14)
Subfamily Sturnirinae				
Sturnira lilium	1		Quintana Roo	< 0.07
Sturnira ludovici	1	1	Costa Rica	< (0.06–0.13)
Subfamily Stenoderminae				
Uroderma bilobatum	1	1	Costa Rica	< (0.08–0.14)
Chiroderma villosum	1		Quintana Roo	< 0.09
Artibeus jamaicensis	4	13	Tropics	< 0.07 (0.03–0.14)
Artibeus lituratus	2	3	Costa Rica	< 0.07 (0.05–0.09)
Artibeus phaeotis (infant)	1		Quintana Roo	< 0.15
Artibeus toltecus	1	3	Costa Rica	< 0.10 (0.06–0.14)
Subfamily Desmodontinae				
Desmodus rotundus		1	Yucatan	< 0.07
Diphylla ecaudata		1	Yucatan	< 0.09
Family Natalidae				
Natalus stramineus	1		Yucatan	< 0.20
Family Vespertilionidae				
Myotis keaysi	1		Yucatan	< 0.20
Myotis leibii		3	South Dakota	Nil‡
Myotis leibii (infants)	3	2	South Dakota	Nil‡
Myotis lucifugus	3	16	Minnesota	Nil‡
Myotis lucifugus	1		Minnesota	< 0.18
Myotis velifer	1		Kansas	< 0.30
Myotis riparius		1	Costa Rica	0.51
Eptesicus furinalis	1		Yucatan	< 0.14
Eptesicus fuscus	8	6 (+3 unknown)	Minnesota	< 0.07 (0.05–0.25)
Lasiurus ega		2	Yucatan	< (0.08–0.14)
Lasiurus intermedius		1	Quintana Roo	< 0.18
Plecotus townsendii	1		Montana	< 0.30
Family Molossidae				
Molossus ater		1	Yucatan	< 0.08
Molossus sinaloae	1		Yucatan	< 0.07
Promops centralis	1		Yucatan	< 0.09
Eumops glaucinus	1		Yucatan	< 0.09

* Bats were obtained from natural habitats in Yucatan and Quintana Roo, Mexico in April and May, Costa Rica in August and September and various places within the USA primarily during summer. Locality of collection sites is specified to state or country, except where our values represent specimens from two or more tropical localities, in which case locality is designated tropics. Livers were removed immediately after killing, frozen quickly and shipped and held in the frozen state until assayed. Voucher specimens of all species are preserved in the Bell Museum of Natural History.

† Analysed by method of Ayaz *et al.*[6] except as noted, and expressed as μmol ascorbate per g liver per h. Individual whole livers weighing 0.06–1.00 g were homogenised in 5–10 ml of buffer containing 0.2 % sodium deoxycholate. The homogenate was centrifuged at 20,000*g* for 30 min and sample of the supernatant was incubated for 30 min with L-gulonolactone (5.6 mM). We encountered no interference attributable to lactonases present in the homogenate[5], and addition of sodium pyrophosphate[5] did not affect the apparent activity of the enzyme. Ascorbate produced was estimated by the Roe–Kuether colorimetric method. Blanks were made by omitting L-gulonolactone from the incubation mixture. The net absorbance (sample minus blank) was above the value of 0.01, which we consider the minimum absorbance detectable with precision, for only three specimens (0.011, 0.025 and 0.011 for *Pteronotus suapurensis*, *Myotis riparius* and one *Artibeus jamaicensis*, respectively). Calculated values of L-gulonolactone oxidase activity are presented for these three; for all others the net absorbance was less than 0.01 and activities are reported (individual values or means and ranges) as falling below the values calculated for the respective liver weights if the net absorbance has been 0.01.

‡ Analysed by microsomal technique of Chatterjee[5].

of some bat livers. Consequently, we cannot deny unequivocally the presence of enzyme at levels up to the values given in Table 1. These values, however, are similar to those calculated in like manner for guinea pigs[6], a species classically considered to lack the ability to synthesise ascorbate[7].

We do not think that the apparent lack of enzyme activity shown in Table 1 resulted from loss in storage of the livers before analysis because some livers were analysed immediately after removal and others were transported and stored with rodent livers, which invariably exhibited activity levels normal for the species. No relationship was observed within the Chiroptera for change in biosynthetic ability with age (infant *Myotis leibii* and *Artibeus phaeotis* did not have L-gulonolactone oxidase) or sex (note especially *Glossophaga soricina* in Table 1).

Giroud *et al.*[8] demonstrated the presence of ascorbate in adrenals, kidney, and liver of bats of the genera *Plecotus, Rhinolophus* and *Eptesicus* We calculated mean ascorbate levels in mg per g tissue for five pooled samples of each tissue from ten young-of-the-year and two adult *Eptesicus fuscus* caught in late August as follows: adrenal, 0.29; spleen, 0.31; kidney, 0.10; liver, 0.20; testes (seven males), 0 19. Blood of the same bats contained 0.6–0.9 mg ascorbate per 100 ml. These values are comparable with those of mammals known to be synthesisers[8], and together with those for *Myotis lucifugus*[9] they demonstrate that bats are neither deficient in ascorbate nor adapted to survival in the absence of that molecule.

We investigated the hypotheses (1) that bats synthesise ascorbate in some tissue other than liver or (2) that they do so in liver *in vivo* but the reaction is somehow inhibited *in vitro*. Pooled samples of kidney tissue of *Myotis lucifugus* and *Eptesicus fuscus* were examined for L-gulonolactone oxidase using the microsomal[5] and deoxycholate[6] techniques, respectively. No enzyme activity was detected for either species. To test for an inhibitor, an homogenate of liver of *Eptesicus fuscus* was mixed 5 : 1 with one of rat. The enzyme activity of the rat liver was 12.4 μmol per g liver per h when assayed alone and 12.9 μmol per g liver per h when assayed in the mixture with bat liver. The possibility that bats synthesise ascorbate by a pathway that does not involve L-gulonolactone oxidase was not investigated.

The lack of L-gulonolactone oxidase in bat liver is strong presumptive evidence of lack of ability to synthesise L-ascorbic acid Evidence of deficiency on feeding ascorbate-free diets would provide confirmation, but all previously confirmed cases of lack of synthetic ability in vertebrates are due to absence of L-gulonolactone oxidase. We conclude therefore that the bats examined do not synthesise ascorbic acid, and we anticipate that this will prove to be characteristic of all members of the Chiroptera.

In spite of some speculation[10,11], the selective pressures that have resulted in the loss of L-gulonolactone oxidase on at least three occasions during the evolution of the Mammalia are unknown, and not appropriate for discussion in this brief report. Regardless of the specific cause, the ability to synthesise an essential molecule should be lost only when an adequate supply of that molecule is available in the diet. It might then be predicted that species unable to synthesise would have limited potential to exploit new habitats and food sources and ultimately to radiate phylogenetically. Accordingly, the guinea pig is the only known non-synthesising rodent, and the anthropoid apes are relatively limited in number of species and generally are herbivorous or omnivorous Such is not the case for bats. Within our sample alone, species are represented whose primary foods are fish (*Noctilio*), fruit (*Artibeus* and others), pollen-nectar (*Glossophaga*), blood (the desmodontines) and insects (the mormoopids, natalids, vespertilionids and molossids)

The earliest bats were probably primarily insectivorous[12]. Although some chiroptologists would disagree and little fossil evidence exists, bats are most likely monophyletic—they have evolved from some common non-synthesising, insectivorous stock. It follows then that lack of the ability to synthesise L-ascorbate has not been an evolutionary handicap for many bat lineages. Bats may have selected as primary diets foods high in ascorbate, or they may be especially adapted to utilise ascorbate efficiently, or both. One obvious food resource known to be deficient in ascorbate is seeds[13], on which no bat relies for a primary dietary item.

Interaction of Walker 256 mammary carcinoma and foetal rat liver in organ culture inhibits enzyme maturation

WHEN tumour tissue is implanted subcutaneously into an animal the enzymatic composition of the host liver changes so as to resemble that of well differentiated hepatomas[1-4]. When a tumour is implanted into a suckling rat (14–20 d old) the appearance of liver enzymes that occurs normally at that stage of development is severely inhibited[4] by as yet unknown mechanisms. We have investigated whether possible endocrine modification of the host by the implanted tumour is an obligatory step in the enzymatic modification of the host liver. We used cultured foetal liver, a system in which several enzymes have been reported to arise spontaneously[5-7]. Our results show that tumours can exert a direct effect on enzyme maturation of foetal liver in organ culture that is quantitatively comparable with the effect observed *in vivo*; they do not rule out a possible glandular involvement of the tumour-bearing host *in vivo*.

Livers from rat foetuses at 16–19 d gestation were removed aseptically, cut into 1–2 mm³ fragments, rinsed with Waymouth 751 medium and placed in groups of eight on top of 25 mm Metricel membrane filters, type GA-4 (0.8 μm), supported by sterile Gelfoam sponges (Upjohn) previously saturated with medium. Two such arrangements were maintained per 60-mm Falcon plastic culture dish. The solid transplantable mammary carcinoma Walker 256 was treated in the same way

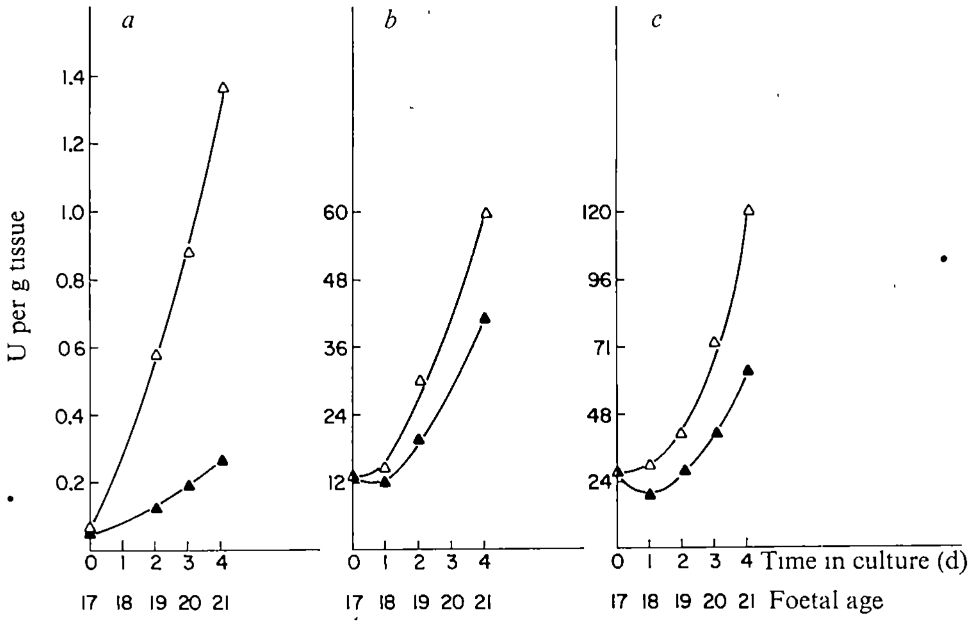

Fig. 1 Enzyme development in 17-d foetal liver explants. Falcon plastic dishes (60 mm) contained 4 ml Waymouth 751 medium supplemented with 10% heat-inactivated horse serum, 100 U of penicillin, 50 µg of streptomycin, 5 µg of fungizone per ml and, where indicated, with hydrocortisone (0.4 µg ml^{-1}). The *p*H of the medium was adjusted to 7.4 by addition of a 7.5% sodium bicarbonate solution and the dishes were incubated in Torbal anaerobic jars at 37 °C in an atmosphere of 70% oxygen, 5% CO_2, 25% nitrogen for a maximum of 5 d with daily changes of the medium. ▲, No additions to culture medium; △, hydrocortisone (0.4 µg per ml). *a*, TAT; *b*, AAT; *c*, arginase.

except that it was placed directly on to the sponges covered by the Metricel filters that supported the liver explants. Microscopy showed that the liver explants were not invaded by the tumour tissue and that the Metricel membranes prevented migration of cellular outgrowth. The viability of the tumour tissue was assessed by following the specific activity of thymidine kinase (EC 2.7.1.21) assayed by the method of Klemperer and Hayes[8], and that of the liver explants by following the accumulation of three enzymes: tryosine α-ketoglutarate transaminase (TAT) (EC 2.6.1.5) assayed by the method of Lin *et al.*[9], aspartate aminotransferase (AAT, EC 2.6.1.1) assayed according to Herzfeld and Greengard[10] and arginase (EC 3.5.3.1) determined according to Geyer and Dabich[11]. In addition, the maintenance of total weight (12–20 mg per filter) and total protein (3–5 mg per filter) for the duration of the culture proved to be a sensitive indicator of viability.

The development of AAT and arginase in the presence and absence of hydrocortisone in 17-d foetal liver explants is shown in Fig. 1. The kinetics of accumulation of these enzymes were similar in explants of 16-d-old foetuses but absolute values were about half of those in 17-d-old embryos. When livers of 19-d-old foetuses were explanted, initial values were higher but rose less sharply during culturing. The response of all three enzymes to hydrocortisone in the medium was the same at all ages. Although animals were time-mated, an 8–10 h uncertainty with respect to age (several litters were needed for each of the experiments reported) was sufficient to make standard deviations seem larger than those inherent in either the enzyme assays or the development of the enzymes in duplicate explants from the same litter. Representative data are therefore shown, and when tumour tissue was cocultured with foetal liver (below) experimental and control explants were from the same litter.

The behaviour of AAT in organ culture is similar to that *in vivo*: measurable levels appear on day 17 of gestation and a significant increase in activity has been reported in response to hydrocortisone[10]. The behaviour of TAT and arginase, on the other hand, differs from that *in vivo*: TAT does not appear until after birth, cannot be induced prematurely by hydrocortisone, and appears prematurely only when the young are delivered surgically before term[12]. Arginase activity can be detected from day 16 of gestation, but cortisol had no enhancing effect, during the prenatal period[13].

When foetal livers were cocultured with Walker 256 carcinoma (Fig. 2) the rate of accumulation of TAT decreased by 40%, and that of AAT by 25%. The development of arginase

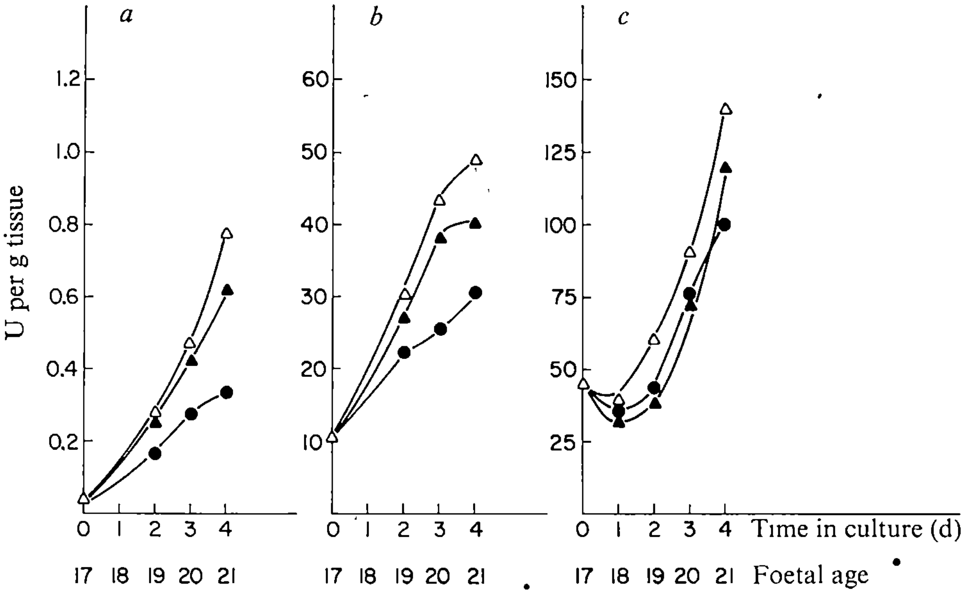

Fig. 2 Enzyme development in 17-d foetal liver explants cultured in the presence of Walker 256 mammary carcinoma. Livers were explanted as described for Fig. 1. All cultures were supplemented with 2 mM glutamine and hydrocortisone (0.4 µg ml^{-1}). ▲, Foetal liver; ●, foetal liver in the presence of tumour tissue; △, foetal liver in the presence of mammary tissue. *a*, TAT; *b*, AAT; *c*, arginase.

was not affected, precluding the interpretation that the tumour exhausted an essential component of the medium. This possibility is further made unlikely because liver explants cultured in the presence of tumour tissue consistently increased in total mass and protein by 15–20%, whereas controls did not.

All culture dishes containing Walker carcinoma (and those serving as controls) were supplemented with additional 2 mM glutamine (in view of the high glutaminase content of tumours) and with hydrocortisone (0.4 µg ml^{-1}). The inhibitory effect of the tumour on the rate of enzyme accumulation in the liver explants did not depend on the presence of the corticoid in the medium; rather, in initial mixed culture experiments without hydrocortisone, enzyme levels in the cocultured liver explants were too low to be measured accurately.

Table 1 Enzyme development in 19-d foetal liver explants

Days in culture	Foetal age	Additions to culture medium: None, Injected	Additions to culture medium: None, Controls	Cortisol (0.4 µg ml^{-1}), Injected	Cortisol (0.4 µg ml^{-1}), Controls
			TAT		
0	19	0.03	0.03	0.03	0.03
1	20	—	—	—	—

3	22	83	59	217	158
4	23	70	71	248	174

Foetuses in one uterine horn were injected with 25 µg cortisol each, 24 h before their livers were explanted as described in the legend to Fig. 1; non-injected foetuses from the other uterine horn served as controls. Activities are given in units per g tissue.

To ascertain whether the inhibition of TAT and AAT accumulation was tumour specific, foetal livers were cultured in conditions identical to those described, but with mammary tissue from a pregnant dam instead of tumour. The activities of all three enzymes were always 10–20% higher than in controls (foetal liver explants alone). We cannot explain this observation; however, a differentiating effect of mammary mesenchyme on tumour tissue explants has been reported[14].

The inhibitory effect of the tumour on the enzymatic maturation of the liver explants was reversible and depended on the continued survival of the tumour in culture. When the sponges supporting the tumour tissue were replaced by empty sponges on day 3 of culture, enzyme accumulation resumed at the rate of controls. Similarly in some experiments in which the tumour did not survive as long as the liver explants (as ascertained by thymidine kinase activity measurements), accumulation of the indicator enzymes resumed at the rate of controls.

Because the cultures containing the tumour had to be maintained in the presence of hydrocortisone to obtain detectable enzyme levels in the cocultured livers, and all three enzymes responded to the hormone with an increased rate of accumulation in organ culture although two of them did not respond in this way *in utero*, it seemed that the corticoid may serve some nonspecific function in the system, perhaps the maintenance of tissue viability, similar to that of certain serum factors[15]. To test this possibility we injected each of several foetuses *in utero* with 25 µg hydrocortisone 24 h before their livers were explanted into media with and without hydrocortisone. The results of a representative experiment (Table 1) show that enzyme levels in cultures from 19-d-old foetuses which had received hydrocortisone *in utero* were similar for 2–3 d in culture to those which were explanted from uninjected controls into medium containing hydrocortisone. The rate of enzyme accumulation in the injected samples then slowed, whereas explants maintained on hydrocortisone with daily medium changes continued to respond with the same rate of enzyme accumulation; those injected and maintained on hydrocortisone showed the greatest response, particularly arginase. When foetuses were injected with hydrocortisone on day 16 of gestation and their livers were explanted 24 h later into media with and without hydrocortisone, the injected hormone was ineffective (data not shown). This argues against the possibility that the injected hormone had some lasting, nonspecific effect; rather it suggests that hydrocortisone has a specific inducing effect if administered when the liver is competent to initiate *in utero* the processes which culminate in enzyme production *in vitro*.

Our findings suggest that the Walker 256 carcinoma produces a diffusable factor (or factors) with an inhibitory effect on the rate of accumulation of some, but not all, enzymes that develop in embryonic liver maintained in organ culture. The effect is specific for Walker carcinoma tissue and its maintenance depends on the continued survival of the tumour in culture. The apparent rapid inactivation of the factor(s) in this system need not signify an inherent instability precluding its isolation; serum factors that withstand remarkably harsh conditions during their purification are known to be inactivated rapidly by cells in culture[16]. While the endocrine state of a tumour-bearing animal is undoubtedly modified, our results show that Walker carcinoma tissue exerts a readily measurable direct effect on developing liver in organ culture, that is without the intervention of endocrine changes. The system described is therefore well suited as an assay for the isolation of the pertinent factor(s) and for the study of its mechanism of action.

Mechanism for suppression of cellular biosynthesis of prostaglandins

BIOSYNTHESIS of prostaglandins (PGs) from unsaturated fatty acid precursors involves a complex sequence of reactions that seem to proceed rapidly in response to physiological stimuli. Studies *in vitro* have revealed a capacity for biosynthesis greater than would be expected from measures of tissue content[1,2] or daily prostaglandin (PG) production[3]. Biosynthesis requires release of esterified precursor from tissue lipids[4,5], and control of the hydrolytic event may be a major means of controlling PG biosynthesis (for example, in brain[6] or spleen[7]). Another possible type of regulation is control of cyclo-oxygenase activity. Many chemical agents have been examined as modifiers of the PG-forming oxygenase (for example, reviews in refs 8 and 9). The enzyme can be inhibited by fatty acids[10] although they appear only in limited amounts in the cytosol. In addition, inhibition of the oxygenation reaction has been observed *in vitro* with added glutathione peroxidase (GSP) and reduced glutathione (GSH)[11–14]. We have further investigated this form of enzymatic regulation, and propose that it inhibits by destroying an essential activator of the oxygenase which forms the PGs and thromboxanes.

Supernatant (BSN) obtained from centrifugation of homogenates of bovine vesicular glands at 105,000*g* for 90 min gave 60% inhibition of oxygenation of arachidonic acid by bovine vesicular gland microsomes, and 40% inhibition of the activity of an acetone powder preparation from sheep vesicular glands. Since the bovine oxygenase showed only 12% of the specific activity of that from sheep, and the supernatant from sheep vesicular glands gave little inhibition of oxygenase preparations, the most active inhibitory and oxygenating preparations were used in subsequent experiments (Table 1). When sodium cyanide, an inhibitor of PG synthesis[15,16], was in the oxygenase assay mixture at a concentration (0.5 mM) that gave about 45% inhibition of oxygenation in the absence of added BSN, a synergistic inhibition was observed that was proportional to the amount of BSN when < 0.1 ml of BSN was present, and was complete with ≥ 0.1 ml of BSN. The BSN was only about half as inhibitory when additional GSH was omitted from the assay, and did not inhibit the oxygenase when 1.0 mM *N*-ethylmaleimide (NEM, which combined with the necessary mercaptan group of GSH) was added. Oxygenase activity could also be recovered when NEM was added to a reaction mixture several minutes after total inhibition by 0.1 ml of BSN. The total extent of reaction before and after addition of NEM was the same for all concentrations of BSN used, indicating that the capacity of the oxygenase for production of PGs and related derivatives was not irreversibly impaired by BSN.

When radioactive eicosatetraenoic acid (150 nmol) was incubated with the oxygenase preparation, 69–74% of the product formed migrated with ^{3}H-PGF$_{2\alpha}$ (R_f = 0.05–0.20) and ^{3}H-PGE$_2$ (R_f = 0.20–0.45) standards, 12–17% with the region associated with PGD$_2$, PGG$_2$ and PGH$_2$ (R_f = 0.30–0.45) and 10–19% with the hydroxy acid standard (R_f = 0.45–0.60). The relative amounts of product formed were similar in the presence of GSH and the BSN with or without NEM present. In the presence of 4 mM $SnCl_2$, 73–80% of the product migrated with PGF$_{2\alpha}$ (R_f = 0.05–0.20) and 6–19% with PGE$_2$ (R_f = 0.20–0.29) standards.

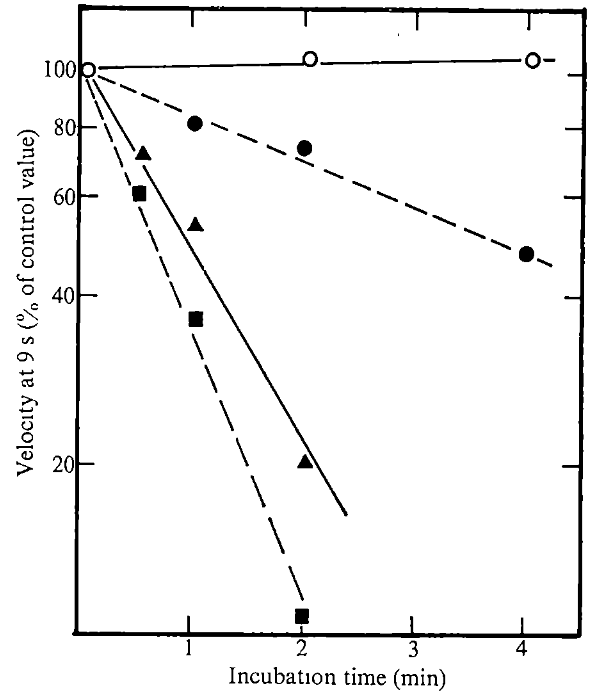

Fig. 1 Time-dependent destruction of the oxygenase activator by BSN and GSP. Activator was generated from 65 μM arachidonic acid with 350 μg of sheep vesicular gland dioxygenase in 3 ml of 0.1 M Tris chloride at *p*H 8.5, containing 0.67 mM phenol and NaCN, as indicated below. After 4 min of reaction and cessation of oxygen consumption, 500 μM GSH and the BSN or GSP solution were added. Then, after various times, the oxygenase reaction was initiated by addition of 350 μg of vesicular gland enzyme, and initial velocities were measured using an oxygen electrode equipped with an electronic differentiator. The value for the oxygenase velocity at 9 s is a measure of the amount of activator[16,18]. ○, 0.5 mM NaCN+heat-treated GSP; ●, 0.5 mM NaCN+120 U of GSP; ■, 1.0 mM NaCN+150 U of GSP, ▲, 0.5 mM NaCN+0.015 ml of BSN.

We have proposed[14,16] that the oxygenase required a hydroperoxide activator and PG production may be inhibited by removal of activator molecules by GSP. Figure 1 shows that very low levels of either BSN or GSP destroy the activator in a few minutes.

The inhibitory agent in the cytosol of bovine glands (BSN) had several properties similar to those of the GSP purified from rat liver[17] or bovine blood[18]. Both GSP and BSN were dependent on added GSH for maximal inhibitory ability (and added NEM,

Table 1 Inhibition of sheep vesicular gland dioxygenase by BSN

BSN was obtained by homogenising 100 g of bovine seminal vesicles in 200 ml of 0.1 M Tris-HCl at *p*H 8.5. The homogenate was centrifuged at 10,000*g* for 15 min and the supernatant was filtered through cheesecloth. This supernatant was centrifuged for 90 min at 105,000*g* and the resultant supernatant was removed and stored at −20 °C for later assay. Assays were made in 3.0 ml of 0.1 M Tris-HCl at *p*H 8.5 (except where otherwise indicated the *p*H 7.0 buffer was 0.1 M EDTA) containing 0.67 mM phenol, 0.5 mM reduced glutathione, 65 μM arachidonic acid and other additions as indicated. Reaction was initiated by addition of 375 μg of phenol-activated sheep vesicular gland enzyme. After 3–5 min, 1.0 mM *N*-ethylmalemide was added to the reaction mixtures. Dioxygenase activity was monitored with an oxygen electrode equipped with an electronic differentiator.

which removes GSH, eliminated inhibition by both); inhibitory in a concentration-dependent manner; synergistic with NaCN in the inhibition of PG formation; heat-labile and non-dialysable, destroying the activator of the oxygenase in a time-dependent manner (Fig. 1).

BSN also appeared most effective as an inhibitor at or near the *p*H optimum for GSP (*p*H > 8.5; see also refs 19–22). There was a slight difference in the amount of $(NH_4)_2SO_4$ required to salt the two inhibitors out of solution: approximately 68% of the total inhibitory ability of the BSN precipitated from solution between 0.33 and 0.50 saturation with $(NH_4)_2SO_4$ whereas about 60% of the measured GSP activity of rat liver supernatant was salted out between 0.45 and 0.65 $(NH_4)_2SO_4$. (Rat liver–GSP was obtained by extraction of protein precipitated in ethanol at −25 °C (ref. 17), whereas the BSN was a high speed supernatant and contained more protein per ml than the liver preparation which could explain the differences.) BSN, like GSP, catalysed the destruction of cumene hydroperoxide in the presence of reduced GSH (8 U peroxidase activity per µl of BSN—see ref. 18 for assay conditions and definition of units).

The apparent K_m for GSH may vary greatly depending on the initial steady-state concentration of the peroxide substrate[22,23], suggesting that as the local physiological concentrations of hydroperoxide substrate approach 1µM the *in vivo* level of GSH (usually between 100 µM and 5 mM (refs 24 and 25) may be close to its K_m for GSP. Thus, metabolic alterations of the intracellular concentrations of GSH within this concentration range could alter directly the effective peroxidase activity and thereby act as an intracellular modulator of the activity of the fatty acid oxygenase(s) that form the PGs and thromboxanes. Homogenisation of a tissue *in vitro* also gives dilution of the cytosolic GSP and GSH to concentrations that are less inhibitory than those *in vivo*.

Formation of PGs *in vitro* has been reported to be inhibited in a dose-dependent manner by a component of the supernatant obtained during the preparation of microsomes from bovine seminal vesicles[26,27] and rabbit renal medulla[28], but the nature of the inhibition was unclear. Inhibition by a soluble component from tissue preparations may also be inferred from the data from other studies with these and other tissues[29–32], that is, total product found in one or more of the PG fractions was significantly less when supernatant was included in the assays. Metabolic enzymes could lower accumulated levels of PG, particularly where the assay involves measurement of final concentrations of PG products (for example, ref. 32).

Although there is insufficient evidence to propose that GSP is the only inhibitor present in supernatant preparations, many assays for PG biosynthesis have included levels of GSH > 0.2 mM (refs 28–31), and a GSP-like activity could account for much of the inhibitor in supernatant reported in some of those *in vitro* studies. The observed effectiveness of the GSH-dependent peroxidase in blocking PG biosynthesis suggests that it has a significant physiological role in the many cell types in which it occurs. Thus, peroxidase activities could suppress PG biosynthesis by destruction of the essential activator as it is formed, so that (depending on the levels of peroxidase and essential cofactor, GSH) some dioxygenase molecules are not activated and therefore cannot participate in PG production. A decreasing concentration of cellular GSH could be an important means for cells to modulate cyclo-oxygenase activity to give increased production of PGs and their related derivatives.

Evidence for the proximity of sweet and bitter receptor sites

ALTHOUGH sweetness and bitterness are generally referred to as two of the common or basic tastes, it is by no means certain that they are, in fact, primary[1]. Furthermore, neurophysiological evidence has shown that response to several of the basic taste stimuli can occur in a single taste cell[2]. Much structural progress in the chemistry of sweetness has been made in the past decade through Shallenberger's hypothesis[3–5] that the sweetness of sugars depends on hydrogen bonds between the sugar molecule and receptor site. Our previous work[6–9] has indicated that sugar molecules and their simple derivatives are nearly always sweet, bitter or bitter–sweet. Bitter–sweet sugar molecules, like certain artificial sweeteners such as saccharin, have both bitterness and sweetness as intrinsic features of their molecules[10]—neither response can be altered by exhaustive stepwise purification of such compounds[10]. Bitter–sweet sugar molecules appear to be 'polarised' on taste receptors[9] so that one end of the molecule binds to sweet receptor sites and the other to bitter receptor sites. It is not clear, however, whether these molecules distribute themselves, some on sweet receptors

*Sweetness is listed as product of peak subjective intensity (*I*, arbitrary scale 00 = zero sweetness to 5 = very sweet) and persistence (*T*) of response for sucrose (S) and methyl-α-D-mannopyranoside (M). Untrained panellists were simply selected on basis of recognising different concentrations employed in this experiment at one sitting Tap water was used for mouth rinsing and immediately afterwards panellists drank 1.0 ml of either sucrose or corresponding methyl-α-D-mannopyranoside solution, recording their subjective intensities on a Telsac Type X moving chart recorder travelling at 12.0 min^{-1} as soon as the solution had been imbibed. Only sweetness was recorded, bitterness being ignored. For tasting after presaturation of bitter receptor sites, panelists kept the 10 ml 0.0048% quinine sulphate solution in mouth for 10 s, then spat out, and immediately drank 1.0 ml of either sucrose or corresponding methyl-α-D-mannopyranoside solution, recording subjective intensity and time as before. All recordings were continued until zero sweetness response was obtained The order of presentation of samples to panellists was randomised. An interval of 1 5 min was allowed between successive corresponding sample tasting, for the comparisons before presaturation, and 5 0 min for comparisons after presaturation. Significance was determined by Student's *t* test.

and some on bitter receptors, or whether a single molecule can span both sweet and bitter receptor sites simultaneously. We now report an experiment designed to distinguish between these possibilities, using a typical bitter–sweet and conformationally defined glycoside, methyl-α-D-mannopyranoside (Fig. 1.).

The subjective intensity of taste response in sweet[11] and bitter[12] molecules is known to be proportional to the logarithm of concentration at presaturation levels[11,12]. We have examined the persistence time (*T*) of the response as well as the peak subjective intensity (*I*) as functions of the concentration of stimulus presented to panellists. The product (*IT*) of these parameters obtained by a continuous trace on a moving chart recorder is a function of the area under the resulting 'taste' curve, and thus total gustatory response. In Table 1, the sweetness values of sucrose and methyl-α-D-mannopyranoside (measured as the product (*IT*) at three different concentrations, are listed before and after presaturation of the taste buds with quinine sulphate solution. At all three concentrations tested a significantly diminished sweetness response after presaturation with quinine sulphate solution is observed with methyl-α-D-mannopyranoside solution, but not with sucrose.

In Table 2 the bitterness values of quinine sulphate and methyl-α-D-mannopyranoside (again measured as the product *IT*) at two different concentrations are listed before and after presaturation of the taste buds with sucrose solution. At both concentrations a significantly diminished bitterness after presaturation with sucrose solution is observed with methyl-α-D-mannopyranoside but not with quinine sulphate. The results in both tables clearly indicate a lowered gustatory response to methyl-α-D-mannopyranoside by our panellists if their tongues are presaturated with either sweet or bitter substances. Indeed the effect at the lower concentration of bitterness investigated was so marked that four out of the five panellists could detect no bitterness at all after presaturation of their tongues with sucrose, whereas in the same conditions their response to a similarly bitter quinine sulphate solution was little affected.

It is possibly still an open question whether a taste re-

*Bitterness is listed as product of peak subjective intensity (*I*, arbitrary scale 0 = zero bitterness to 5 = very bitter) and persistence (*T*) of response for quinine sulphate (Q) and methyl-α-D-mannopyranoside (M). The method used was exactly as before, but for tasting after presaturation, panellists kept 10 ml 50% sucrose solution in mouth for 10 s before spitting out. An interval of at least 20 min was allowed between successive corresponding sample tasting, and significance was again determined by Student's *t* test.

sponse can be simply and mechanistically explained in terms of bonding forces between a stimulus molecule and a receptor, or whether a more complicated psychological explanation based on the decodifying of perceptual information[1] might give a truer description of the phenomenon. Many advances have been made[6–9,13–15] on the basis of the former hypothesis, working on the assumption that the sweetness of sugars arises from the existence of AH,B systems in their molecules which govern their ability to hydrogen bond to taste receptors. Sugars generally possess several possible α-glycol groupings meeting Shallenberger's[3–5] requirements for the AH,B system and with oxygen–oxygen interorbital distances of 2.86 Å, but evidence has accrued[6–9,13–15] to implicate the third and fourth hydroxyl groups of aldohexopyranosyl structures as having a significant and particular role in the sweetness response. By contrast that area of the molecule which surrounds the anomeric centre does not appear to influence sweetness[6,9,13] but does affect bitterness and these distinct gustatory features seem to be characteristic of a considerable number of different glycoside molecules[9,13].

Not all receptor sites are on the same receptor cell, and Ogawa *et al.*[16] have reported that 25% of fibres tested from the chorda tympani of rat and hamster responded to all four basic tests. Frank and Pfaffmann[17] have also shown in the glossopharyngeal nerves of rat that the majority of the fibres are not completely specific for any of the basic tastes, and only a small percentage responded to both sucrose and quinine. It is therefore clear that taste cells may vary in degree of specificity.

The results of this experiment can be interpreted on the basis of our hypothesis that sugar molecules are 'polarised' on taste receptors[8], to mean that the bitter/sweet glycoside attaches itself by a chelating action to the sweet and bitter receptor sites simultaneously. Impairment of either mode of attachment by presaturating the taste receptors with sweet or bitter molecules results in a lowered response. This also suggests that at least some of the sweet and bitter receptor sites might be extremely close to one another, probably within 3–4 Å.

Uptake and catabolism of low density lipoprotein by human lymphocytes

BROWN and Goldstein[1,2] have shown that when cultured human fibroblasts are incubated in the presence of low density lipoprotein (LDL), they take up some LDL, the apoprotein of LDL (apoLDL) is catabolised and cholesterol synthesis is inhibited. Experiments on the uptake of LDL as a function of LDL concentration have led to the conclusion[1,2] that normal fibroblasts have genetically controlled surface receptors with high affinity for apoLDL and that uptake of LDL by the receptors is essential for the regulation of cholesterol synthesis. These findings raise the possibility that receptor-mediated uptake by fibroblasts, and perhaps by other cells[3,4], has an important role in the regulation of apoLDL catabolism and of cholesterol synthesis *in vivo*. But the concentration of LDL protein required to saturate the LDL receptors on cultured fibroblasts (about 50 μg ml^{-1}) is less than half the probable concentration in interstitial fluid[5]. Moreover, whereas cultured fibroblasts from patients with familial hypercholesterolaemia (FH) in the homozygous form synthesise cholesterol at 50 times the normal rate, the rate of synthesis of cholesterol in the whole bodies of FH patients is usually normal[6] or subnormal[7]. For these reasons it seemed desirable to study the binding and catabolism of LDL by uncultured human cells. We used circulating lymphocytes because they can be obtained readily and repeatedly from healthy human subjects. Our results show that uncultured lymphocytes exhibit high capacity surface binding of LDL, but the binding curves show no evidence for the presence of high affinity receptors for LDL.

Lymphocytes, prepared from 300 ml of freshly drawn heparinised blood by density-gradient centrifugation[8], were washed four times in Eagle's MEM. LDL (density 1.020–1.050), prepared from normal human subjects[9], was labelled with ^{125}I by the iodine monochloride method[10]. Of the total ^{125}I in the labelled LDL, 5–7% was extractable with chloroform–methanol (2 : 1, v/v).

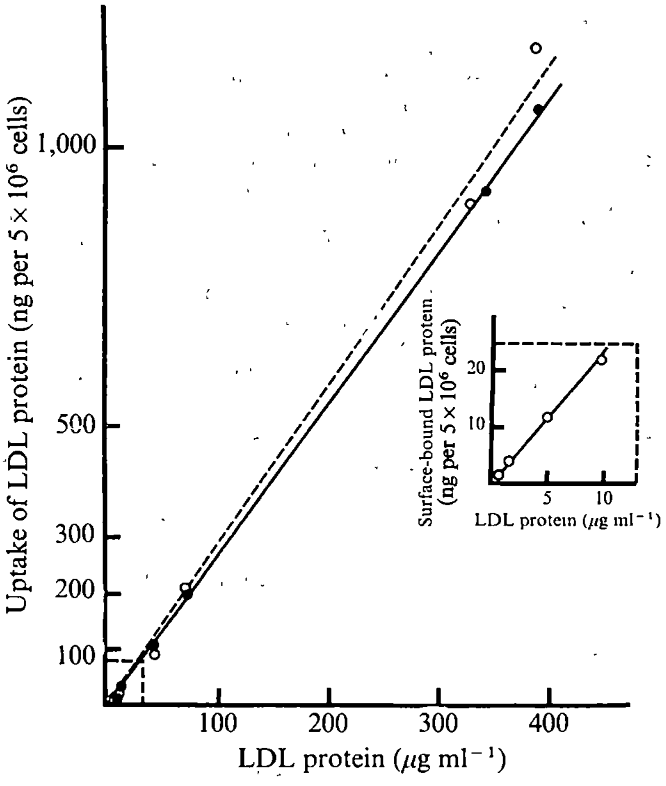

Fig. 1 Uptake of surface-bound (○) and internalised (●) LDL protein by human lymphocytes as a function of LDL concentration in the incubation medium. Inset shows expansion of curve for surface-bound LDL protein at low LDL concentrations. After incubation in duplicate with labelled LDL the cells were washed seven times before radioassay. Surface-bound and internalised LDL protein in the washed cells were estimated from the amounts of non-lipid ^{125}I releasable and non-releasable by trypsin respectively. The specific radioactivity of the LDL protein in the incubation medium was used to convert c.p.m. into ng of LDL protein taken up. Values shown are from one of five experiments with lymphocytes from five normal subjects. Experimental details are given in the text.

Binding of the labelled LDL by lymphocytes was investigated by incubating suspensions of cells 5×10^6 cells in 1 ml of MEM containing 1% bovine serum albumin (BSA) for 2 h at 25 °C in plastic tubes in the presence of ^{125}I-LDL. The cells were then separated from the medium by centrifugation. Radioactive breakdown products of the labelled apoLDL in the medium were estimated as trichloroacetic acid (TCA)-soluble radioactivity in the supernatant, after correction for radioiodide[11]. The cells were washed seven times with MEM to remove loosely adsorbed radioactive particles, transferred to fresh plastic tubes and assayed for radioactivity. Lipid-free radioactivity in the washed cells was fractionated into surface bound (^{125}I released by brief incubation with trypsin) and internalised (^{125}I not released by trypsin), essentially by the method of Bierman *et al.*[11].

Table 1 Effect of heparin on trypsin-releasable LDL protein bound to lymphocytes

Treatment	Incubation time (h)			
	1	3	4	5
No heparin	244	238	201	213
Heparin at 3.5 h			260	

All values are expressed in ng of LDL protein bound per 5×10^6 cells and are means of duplicate incubations. Lymphocytes were prelabelled by incubation with ^{125}I-LDL at 25 °C for 2 h in MEM containing 1% BSA. Loosely bound LDL was removed from the cells by repeated washing. Duplicate tubes containing the washed labelled cells were incubated for 1, 3, 4 and 5 h. Heparin (10 mg ml^{-1}) was added to one pair of tubes after 3.5 h and the tubes were incubated for a further 30 min. The amount of trypsin-releasable LDL protein bound to the cells at each interval was determined as described in the text. Binding of LDL by cultured fibroblasts has usually been studied at 4 or 37 °C. Our incubations were carried out at 25 °C because at this temperature lymphocytes catabolise apoLDL, while remaining viable for longer than at 37 °C.

When normal lymphocytes were incubated for 2 h with ^{125}I-LDL, uptake of trypsin-releasable LDL protein and of LDL protein not released by trypsin were both directly proportional to the concentration of LDL in the incubation medium over the range from 0.5 to 380 μg of LDL protein per ml (Fig. 1). No inflection in the curve relating uptake to LDL concentration could be discerned, even at the lowest concentrations (Fig. 1, inset). Thus the binding curves obtained in the conditions of these experiments gave no indication of the presence of high affinity LDL receptors with saturation at about 50 μg of LDL protein per ml. In all experiments, about half the total LDL protein taken up by the cells was internalised by the end of the incubation. There was some variation in the amount of LDL protein taken up at a given LDL concentration by lymphocytes from different normal subjects, but almost identical results were obtained when LDL from different subjects was tested against a single preparation of lymphocytes.

The accumulation of TCA-soluble radioactivity derived from the labelled LDL in the medium was determined after 2-h incubations with lymphocytes from normal subjects. In five preparations of lymphocytes the accumulation of radioactive breakdown products, expressed as a percentage of the total cell-associated radioactive protein (surface-bound plus internalised) recovered at the end of the incubation, averaged 4.8 ± 2.0 (s.d.) (range, 1.8–6.9).

The apparent lack of high affinity LDL receptors on lymphocytes could be due to irreversible saturation of binding sites by LDL before the cells are separated from the blood plasma. The binding curves for trypsin-releasable apoLDL, however, suggest that lymphocytes differ from cultured skin fibroblasts in being able to bind LDL to their surfaces by a mechanism that is not saturated at concentrations approaching 400 μg of apoLDL per ml. High capacity binding of LDL by lymphocytes was investigated further in the experiment shown in Table 1. Lymphocytes were incubated for 2 h at 25 °C in MEM containing 1% BSA and radioactive LDL (500 μg of apoLDL per ml). The cells were then washed seven times and incubated again for increasing periods in MEM containing 1% BSA but no radioactive LDL. Surface-bound LDL protein was assayed at each interval by the methods described above. There was no significant decrease in surface-bound LDL protein during the 5 h of incubation. When heparin (known to displace LDL from the LDL receptors on cultured fibroblasts[12]) was added to the cell suspension after incubation for 3.5 h, there was no displacement of surface-bound LDL protein during incubation for a further 30 min.

These results show that lymphocytes resemble cultured skin fibroblasts in their ability to take up LDL from an incubation medium and to degrade apoLDL. But lymphocytes seem to differ from cultured fibroblasts in being able to bind LDL to high capacity sites that are accessible to trypsin, but from which LDL cannot be displaced by heparin or by incubation in an LDL-free medium for 5 h. A surface-binding mechanism for LDL with high capacity seems more appropriate for circulating lymphocytes than one which is saturated at a concentration of 50 μg of apoLDL per ml, since the concentration of apoLDL in normal human plasma is at least 600 μg per ml.

Nuclear retention of receptor–oestrogen complex and nuclear acceptor sites

OESTROGEN-SENSITIVE cells contain cytoplasmic macromolecules called receptors[1,2]. They bind oestrogen to form complexes which are translocated to the nucleus where they may bind to specific acceptor sites[3–5]. This interaction of receptor–hormone complex with nuclear acceptor sites is assumed to be responsible for the stimulation of RNA, DNA and protein synthesis that results in growth of the tissue[3–5]. The demonstration of nuclear acceptor sites has been difficult and controversial[6,7]. We present here evidence that a limited number of receptor–oestrogen complexes are bound in the nucleus of rat uterine cells and that these sites may be specific nuclear acceptor sites.

Several investigators have shown that nuclear binding of receptor steroid complexes is a saturable phenomenon, thus suggesting that specific acceptor sites exist[7–14], while others claim that limited numbers of specific nuclear sites do not exist and that nuclear saturation is an artefact[6,15,16]. Much of this conflict probably stems from the difficulty inherent in the detection of a small number of specific binding sites in the presence of a large number of nonspecific sites[17].

This is especially true in view of the very "sticky" nature of the receptor–oestrogen complex after exposure to elevated temperatures (20–30 °C) at physiological salt concentrations[18]. The dissociation constant (K_d) for the binding of the receptor–oestrogen complex to various types of nuclei and non-biological surfaces, including glass, is 10^{-9} M at 25 °C (ref. 18). Thus, studies of the binding of the receptor–oestrogen complex to nuclei, chromatin and/or DNA in cell-free systems are susceptible to the error introduced by the masking effect of nonspecific binding.

Although the demonstration of nuclear acceptor binding is difficult *in vitro*, we have shown that a limited number of nuclear binding sites are involved in the production of maximal uterine growth[4,5,19]. We have also demonstrated that the long term retention of 1,000–3,000 receptor–oestrogen complexes per cell is a requirement of uterine growth[19,20]. Since uterine cells contain 15,000–20,000 receptor sites in the cytoplasm, it is apparent that only a fraction of these are required for maximal growth responses. These concepts and experiments are summarised in Fig. 1. We have suggested that the long term retention of the receptor–oestrogen complex in the nucleus is due to the binding of these complexes to a limited number of nuclear acceptor sites and that retention at these acceptor sites for more than 4–6 h is a requirement for true growth[5,21].

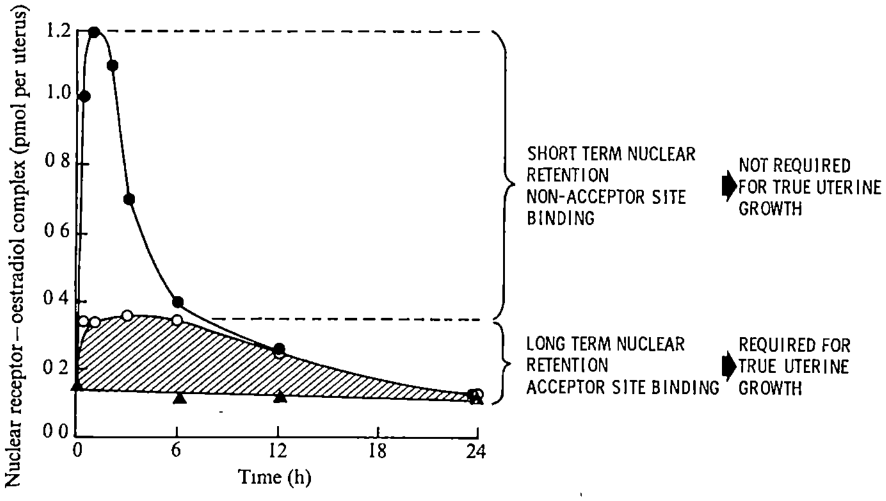

Fig. 1 Relationship between nuclear retention of the oestrogen receptor and uterine growth. Immature rats, 21–23 d old, were injected with either 0.1 or 2.5 μg of oestradiol and the accumulation and retention of the oestrogen receptor by the uterine nuclear fraction was examined by the ^{3}H-oestradiol exchange assay[4,26]. Uterine growth responses (DNA, RNA and protein content; wet and dry weight) were measured 24–48 h after injection (data not shown, see refs 4, 5, 19 and 20), and were stimulated maximally by 0.1 μg of oestradiol[4,5,19,20]. Therefore we conclude that 0.1–0.2 pmol of receptor per uterus is required for the stimulation of true uterine growth[20]. ●, 2.5 μg of oestradiol; ○, 0.1 μg of oestradiol; ▲, saline.

To test this hypothesis further we have used salt extraction of uterine nuclei to examine for differential extractability of the receptor–oestrogen complex. The rationale for the use of this technique was based on the observation, by several investigators, that extraction of nuclei with 0.3–0.4 M KCl does not remove all the nuclear-bound oestrogen[22–24], suggesting that some receptor–hormone complexes are bound more tightly than others. Immature rats 21–23 d old were injected with either a small dose (0.1 μg) or a large dose (2.5 μg) of oestradiol-17β. The animals were killed and their uteri removed 1 or 6 h later. A nuclear pellet was prepared by centrifugation of a uterine homogenate (30–50 mg ml^{-1}) at 800*g* for 10 min[25]. Although purified nuclei were not used, they behave in a fashion similar to that of this crude nuclear preparation (to be published elsewhere). The nuclear fraction was washed twice with cold TE buffer (0.01 M Tris, 0.001 M EDTA, *p*H 7.2, 4 °C). Salt extraction was performed by adding various concentrations of TK buffer (0.01 M Tris and 0.1–0.6 M KCl, *p*H 8.0, 4 °C) to the nuclear pellet with the mass to volume ratio maintained at 30–50 mg ml^{-1}. The nuclear pellets were resuspended in TK buffer and allowed to stand on ice, with mixing every 5–10 min, for 30 min. Nuclear fractions were centrifuged at 800*g* for 10 min and the KCl extract was decanted. TE buffer was added to the nuclear pellet (30–50 mg ml^{-1}) and the pellet was resuspended. If necessary, resuspension was accomplished by rehomogenisation of the pellet with a glass–Teflon homogeniser. The nuclear suspension was then added to small assay tubes (5–10 mg per tube) and the quantity of receptor in the nuclear pellet was measured by ^{3}H-oestradiol exchange[25].

The uterine nuclear fraction from rats that received 2.5 μg of oestradiol 1 h before they were killed contains a large number of receptor sites which are extractable with KCl concentrations less than 0.4 M (Fig. 2*a*). The quantity of receptor which remains in the nuclear fraction after exposure to KCl concentrations of 0.4 M or greater is approximately 0.1 pmol per uterus or 1,400 sites per cell. Thus, this small number of KCl-resistant receptor sites could represent those receptor sites which exhibit long term nuclear retention (Fig. 1). If this were true, the number of

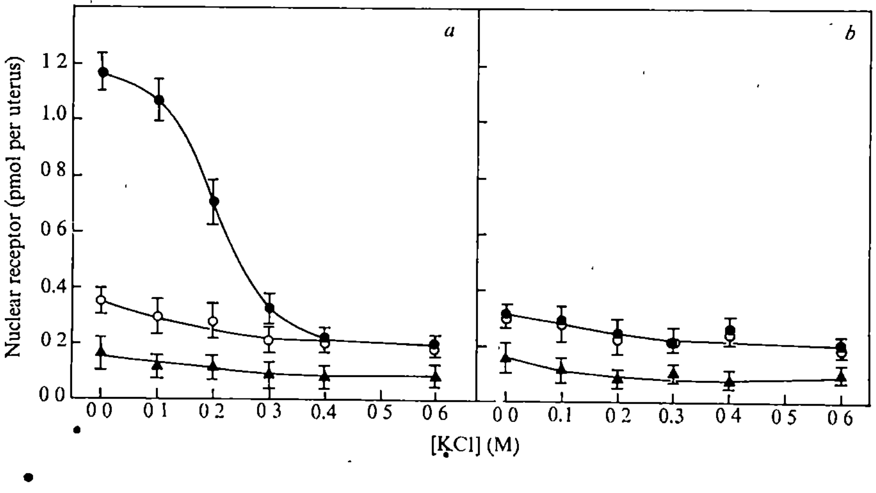

Fig. 2 Differential salt extraction of nuclear-bound oestrogen receptor. Immature rats were injected with oestradiol as described for Fig. 1. Uterine nuclear fractions were prepared 1 and 6 h after injection and differential KCl extraction was performed as described in the text. After extraction, the quantity of receptor which remained in the nuclear fraction was measured by the ^{3}H-oestradiol exchange assay[25]. *a*, 1 h; *b*, 6 h. Symbols as for Fig. 1.

KCl-resistant sites in animals receiving the large dose of hormone should equal the number receiving the small dose, since both doses produce the same number of long term retention sites (Fig. 1). As Fig. 2*a* shows, this seems to be the case. Likewise the number of KCl-resistant sites should be equal 6 h after injection of either dose of oestrogen and should be approximately the same as the number 1 h after the small dose. This also is the case, as Fig 2*b* shows. Therefore, we conclude that the number of receptor sites which remain in the nucleus after 0.4 M KCl extractions, are correlated with the number of sites which exhibit long term nuclear retention. The differential extraction of the receptor–oestrogen complex by KCl may reflect the binding of these complexes to different types of nuclear sites. Most (80–90%) of these nuclear receptor binding sites are of low affinity and extractable with KCl, whereas a minority (10–20%) are of high affinity and are non-extractable sites.

Other observations have suggested that receptor–hormone complexes manifest different characteristics once they have undergone nuclear binding. The rate of dissociation of the receptor–oestrogen complex is much slower when bound to chromatin than when free[26,27]. DeHertogh has observed a small pool of nuclear bound receptor *in vivo* which exhibits a relatively slow rate of oestradiol exchange when compared with the majority of receptor[23]. We have also observed two rates of exchange of the receptor–oestrogen complex when it is bound to the nucleus (unpublished). The exact relationship of these various observations to these reported here are not clear but they may reflect conformational changes in receptor–oestrogen complexes attendant on their association with specific nuclear acceptor sites. Such conformational alterations might result in associations of great affinity between receptor–hormone complexes and acceptor sites, thereby accounting for their resistance to KCl extraction. Since the number of these KCl-resistant nuclear sites is identical to that number of sites required for maximal uterine growth, we propose that these binding sites in the nucleus represent specific acceptor sites.

Interferon action may not be effected by induction of a cellular ribonuclease

Treatment of animal cells with interferon or polyinosinic–polycytidylic acid (pI : pC) can prevent multiplication of animal viruses. In the case of most of such viruses the interferon action consists of an inhibition of the viral translation. For some viruses, such as the DNA-containing Simian virus 40 (SV40), there is evidence for direct inhibition both of transcription[1–3] and translation[4,5]. Marcus *et al*[6] have shown, in chick embryo fibroblasts (CEF), that interferon or pI: pC are able to induce membrane-bound alkaline RNase activity. It was therefore proposed that degradation of viral RNA by membrane-associated RNase is indicative of a unifying concept of interferon action[6]. We attempted to determine whether the induction of interferon is paralleled by an induction of membrane-associated RNase activity in CEF and in primary African green monkey kidney (AGMK) cells. Our results show RNase induction in CEF but not in AGMK cells.

We have found a relatively high level of RNase associated with the membranes from unstimulated CEF compared with membranes from AGMK cells (see Table 1 and Fig. 1). Previous stimulation of CEF with pI : pC resulted in a sevenfold increase in RNase level. This level in the assay mixture (0.25 ml), containing 4 μg membrane protein, is equivalent to the activity of 30 ng ml^{-1} bovine RNase. These data obtained using CEF agree well with the results of Marcus *et al.*[6]. Stimulation of AGMK cells with pI:pC, however, failed to induce a significant increase in RNase level in those cells. Similar results with both CEF and AGMK cells were obtained when membranes were prepared according to the method of Joklik *et al.*[8].

The RNase induced in CEF also proved to be active using host-specific RNA as a substrate, indicating that the RNase does not show a specificity for viral RNA; this might be expected if it were involved in the action of interferon. We are, therefore, able to confirm the findings of Marcus *et al.*[6] for CEF, but we cannot support the

Table 1 Induction of interferon and isolation of membranes from CEF and AGMK cells

Interferon induction*		Membrane isolation	
Cell type and DEAE–dextran treatment (μg ml^{-1})	pI : pC treatment (μg ml^{-1})	Total membrane protein in 10^8 cells† (μg)	Membrane protein in 0.25 ml of RNase assay (μg)
AGMK	0	440	14.8
500	20	340	15.0
CEF	0	270	4.0
10	2	285	4.2

Membranes were prepared in discontinuous sucrose gradients[6,7]. Seven unequal membrane bands were visible. Band 3 (from top) consisting of a layer of smooth membranes, and band 4, containing rough and smooth membranes[7], were combined. These fractions were subsequently subjected to RNase assay. Substrates in tests[1] were ^{3}H-uridine-labelled AGMK cell RNA and *in vitro* transcribed ^{3}H-SV40 cRNA.

* Cells were treated with the mixture of DEAE–dextran and pI : pC for a 15-min period 18 h before membrane isolation[3]. This treatment renders more than 99% AGMK cells resistant to an infection with SV40 (multiplicity of infection = 10) and renders CEF resistant to infection with vesicular stomatitis virus (multiplicity of infection = 1) for a period of 24–48 h.

† Gradient fractions 3 and 4 (ref. 7) were combined.

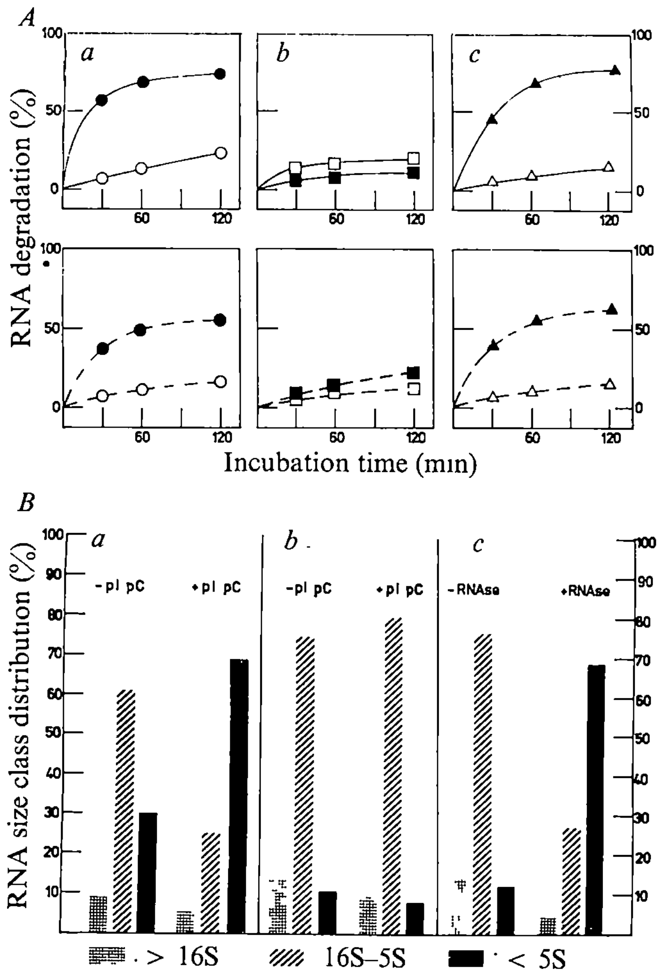

Fig. 1 *A*, Degradation of ^{3}H-RNA after incubation with membrane fractions from *a*, CEF (○, ●) and *b*, AGMK cells (□, ■) pretreated with pI : pC (closed symbols) and untreated (open symbols). Assay mixture contained (total volume 0.25 ml) 0.1 ml membrane protein preparation (Table 1), 0.1 M Tris-HCl (*p*H 8.2), 7.5 mM Mg^{2+}, 1 mM EDTA, and 2.5×10^3 c.p.m. ^{3}H-RNA substrate. Incubation temperature was 37 °C. Substrate was ^{3}H-labelled SV40 cRNA[9] (specific activity 1×10^4 c.p.m. μg^{-1}, ———); and ^{3}H-RNA from ^{3}H-uridine-labelled AGMK cell RNA (specific activity 1.5×10^4 c.p.m. μg^{-1}, – – – – –). Degradation of ^{3}H-RNA during incubation was assayed by scintillation counting of TCA precipitates on Whatman GF/C filters. *c*, Controls: incubation with 30 ng ml^{-1} bovine RNase (EC 3.1.4.22; ▲) and without RNAse addition (△). *B*, Distribution of three ^{3}H-SV40 cRNA size classes after 120-min incubation period with membrane protein (Table 1) from pI : pC-treated (+pI : pC) and untreated (−pI : pC) CEF (*a*) and AGMK cells (*b*) *c*, Controls: incubation with bovine RNase as above. Size classes of ^{3}H-SV40 cRNA were determined by centrifugation in formaldehyde–sucrose gradients[9].

generalisation drawn from this phenomenon that resulted in the unifying concept of interferon action.

An inhibition by interferon of SV40 tumour antigen formation in monkey cells microinjected with *in vitro* transscribed SV40-specific RNA has been found[4,5]. In terms of this inhibition, the failure of pI : pC to induce in AGMK cells a membrane-associated RNase activity, suggests that inhibition of translation is unlikely to be affected by induction of membrane-associated RNase. It has also been found that interferon treatment is also ineffective in inducing RNase activity in embryonic hamster cells. P. I. Marcus (personal communication) has obtained the same results with cells from quails and ducks.

We thank Miss Erika Koch for assistance and Dr H. Werchau for advice in preparing membranes. Supported by the Deutsche Forschungsgemeinschaft.

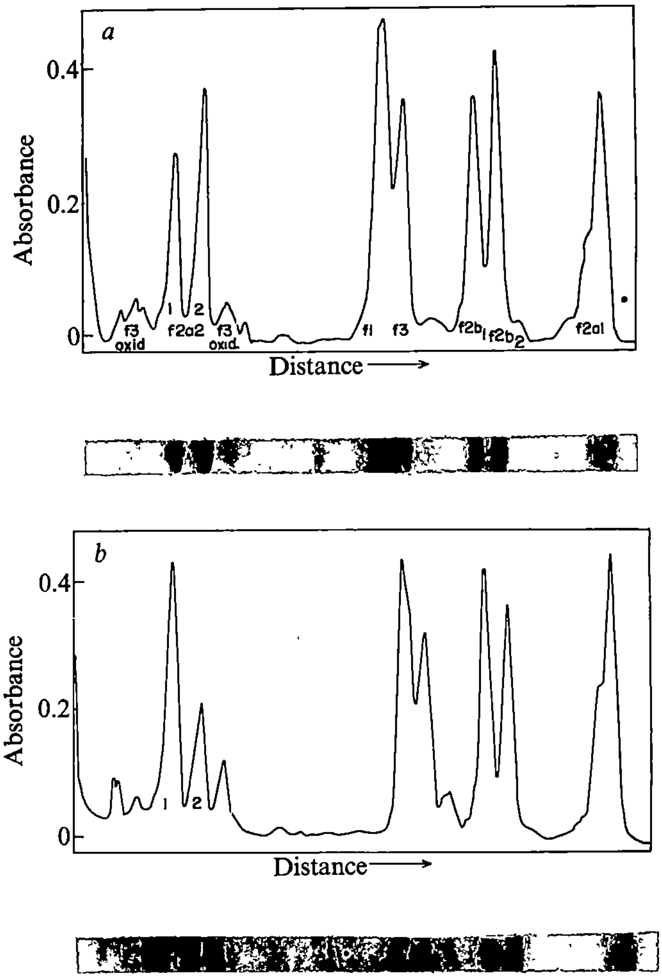
Changes in histone f2a2 associated with proliferation of Friend leukaemic cells

HISTONE–HISTONE interactions with DNA form the basic structural unit of chromatin[1–3], and quantitative changes in the cellular histones correlate with alterations in chromatin structure[4,5]. More subtle changes in chromatin structure follow chemical modification of the histones. These changes may enable genes to assume proper configuration for specific regulation by the non-histone proteins.

Growth of Friend cells *in vitro* with 1–2% dimethylsulphoxide (DMSO) induces globin mRNA synthesis[6,7], the appearance of erythrocyte membrane antigen[8], an increase in haem synthesis and iron uptake[8], an alteration in purine metabolism[9] and morphological changes characteristic of erythroid differentiation[10]. For this response the cells must complete S phase in the presence of 1–2% internal concentration of DMSO[11]. Evidence suggests that DMSO or a metabolic product acts at the level of the chromatin, causing biochemical and physical alteration in DNA–protein interactions[12–14]. If this is true, perhaps the ability of the cell to respond to DMSO depends on a particular chromatin structure. We have established DMSO-inducible and DMSO-non-inducible cell lines *in vitro* from subcutaneous tumours derived from a Friend leukaemic spleen in DBA/2J mice. Analysis of the histones from these cell lines has demonstrated a striking difference in histone f2a2 during establishment of the lines in culture, especially when DMSO-responsive and unresponsive cells are compared.

In acid–urea gels[15], no difference in the kinds or amounts of histones from the different cell types was found. Separation on acid–urea Triton gels[16,17], however, resulted in a finer resolution of the histones, and demonstrated a marked difference in the f2a2 histone subfractions from different Friend leukaemic cells (Table 1). In these gels, histone f2a2 from normal spleen and liver tissue separated into two fractions, $f2a2_1$ and $f2a2_2$, in a ratio of 3 : 1 (Table 1). A similar f2a2 ratio was found for leukaemic spleen tissue or subcutaneous tumour cells taken from the mouse. Friend tumour cells established as *in vitro* cell lines (for example, TP46, TP63), however, showed an increase in $f2a2_2$ and a $f2a2_1 : f2a2_2$ ratio of about 2 : 1. These freshly established cell lines were unresponsive to DMSO (Table 1). After several months' passage in culture, these cell lines began to show a response to DMSO with synthesis of haemoglobin. Coincident with this change in response to DMSO was a further increase in $f2a2_2$ with the ratio of $f2a2_1 : f2a2_2$ now approaching 1 : 1 (Fig. 1, Table 1). Less extensive differences were observed in f2b and f3 histones. The f2a2 ratio was not altered when DMSO-responsive or unresponsive cells were grown subcutaneously into a tumour in a mouse (C17, Table 1). Furthermore, in contrast to the gradual adaptation of Friend tumour cells to tissue culture, these tumour cells derived from tissue culture, with increased $f2a2_2$, adapted immediately to growth *in vitro* and retained their original response to DMSO.

Fig. 1 Histones from C17 cloned cell line (*a*), and leukaemic spleens (*b*). Tissue culture cell lines were obtained from tumours initiated by placing a piece of Friend leukaemic spleen subcutaneously in a mouse. Cells were grown in basal media, Earle's salts (Gibco) containing penicillin and streptomycin and 15% foetal calf serum. For isolation of nuclei and histone extraction, we used the following procedure. Cells collected by centrifugation were resuspended at 10^8 cells per ml in buffer 1 (0.05 M Tris-HCl, *p*H 7.5, 5 mM $MgCl_2$, 0.02 M KCl, 0.25 M sucrose, 0.1 mM phenylmethylsulphonyl fluoride (PMSF), 5 mM sodium bisulphite) and incubated at 4 °C for 5 min before being sedimented by centrifugation (5 min at 2,500 r.p.m. in a SS34 rotor (Sorvall)). This procedure was repeated. Cells were then suspended in 10 volumes of buffer 2 (5 mM Tris, *p*H 7.1, 5 mM $MgCl_2$, 0.05 mM dithiothreitol, 0.1 mM PMSF) and Triton X-100 was added to a final concentration of 1%. After 10 min, the nuclei were sedimented by centrifugation at 2,500 r.p.m. for 10 min (SS34 rotor), washed in buffer 2 without Triton and suspended in 2.2 M sucrose, 1 mM $MgCl_2$, 0.1 mM dithiothreitol and 1 mM PMSF. Centrifugation at 40,000*g* for 1 h in the SW27 (Beckman) sedimented the clean nuclei to the bottom of the centrifuge tube. The purified nuclei were washed twice with 0.14 M NaCl, 0.01 M Tris at *p*H 7.5 before extracting them three times for 1 h each with 0.4 N H_2SO_4 at 4 °C. The histones were precipitated from the combined supernatants by addition of 5 volumes of 95% ethanol and placed at −20 °C overnight. Each histone class in the Triton gels was identified by two methods. (1) Individual histone fractions were extracted by a selective chemical extraction described by Johns[22]. The purity of the fractions was checked by their separations on acid–urea gels[15]. The same individual histone samples were then separated on the Triton–acid–urea gels and their migration was identified. (2) Large diameter Triton gels were prepared on which 1 mg of protein was separated. The gels were sliced into 2-mm sections from which the histones were extracted overnight in 0.15 M NaCl. The location of each histone was determined by assaying each fraction with individual anti-histone antisera in the complement fixation assay described by Stollar and Ward[23]. For this figure, 25 µg of histone was separated on 12% polyacrylamide gel containing 8 M urea and 6 mM Triton X-100[16,17]. Bands 1 and 2 are $f2a2_1$ and $f2a2_2$, respectively. The gels were stained with 0.4% Amido Black and acetic acid : methanol : water (1 : 5 : 14) and scanned at 570 nm with a spectrophotometer (Beckman).



Many different DMSO-responsive cell lines of Friend leukaemia, including the original 745 line from C. Friend, have this altered f2a2. The change in the ratio of the f2a2 subfractions seems to be a prerequisite for the ability of the cells to respond to DMSO. The f2a2 ratio does not change when the cells respond to DMSO.

With increasing time in culture, previously unresponsive cell lines began to respond to DMSO and to show an increase in $f2a2_2$ and concomitant decrease in $f2a2_1$. An uncloned cell line, TP46, established from passage 46 of a leukaemic subcutaneous tumour, was unresponsive to DMSO and retained an $f2a2_1 : f2a2_2$ ratio of 2 : 1 when examined at passages 5, 10 and 18. At passage 36, 10 weeks later, however, the cell line responded to 1.5% DMSO and demonstrated an increase in $f2a2_2$ (Fig. 2). Four cloned cell lines, C7A→D, showing different relative responses to DMSO, were derived from another cloned cell line, C7, established from passage 25 of uncloned line TP32. C7 was initially unresponsive to DMSO but began to show a response after several months' passage in tissue culture. Clone C7C did not synthesise detectable levels of haemoglobin when cultured in 1–2% DMSO. In contrast, C7D responded well to small amounts of DMSO. C7A and C7B were intermediate in their response. Morphologically, all cell lines were similar. Analysis of the histones in these cell lines showed a direct correlation

Table 1 Percentage of each f2a2 subfraction in the total f2a2

	DMSO response	% f2a2 Histone in total histone	% Subfractions in total f2a2		
			$f2a2_1$	$f2a2_2$	$f2a2_1/f2a2_2$

Histones were separated on 12% polyacrylamide gels containing 8 M urea and 6 mM Triton X-100. The percentage of each f2a2 subfraction was determined by weighing photocopy paper of each histone peak from a densitometer tracing and dividing that by the combined weight of both subfractions. The amount of bound dye was directly proportional to the amount of protein in each band (< 20 µg) (ref. 20). TP, tumour passage; +, relative amount of haemoglobin produced in response to DMSO.

* Original line 745.

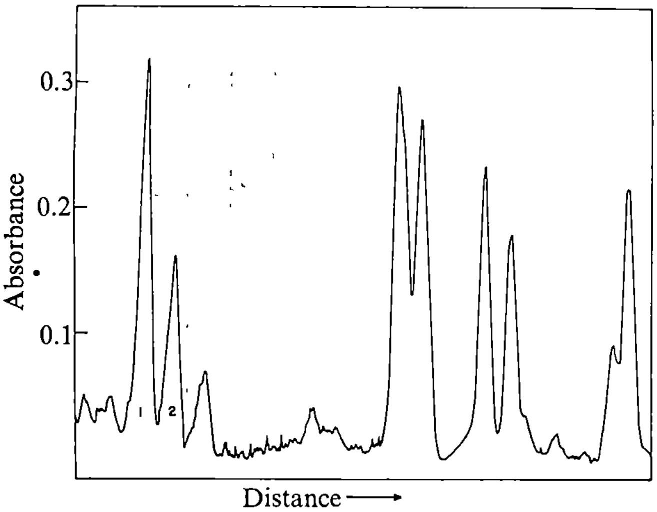

Fig. 2 Histones from uncloned cell line (TP46P18) were extracted and separated as described in the legend to Fig. 1.

between the amount of haemoglobin synthesised in response to DMSO and the amount of $f2a2_2$ (Fig. 3). The results from C7A and C7B may represent an average from responsive and unresponsive cells now present in these originally cloned lines or a decreased DMSO response in all cells. The fact that both types of cells were cloned from the original cloned C7 line suggests that with time in tissue culture a change towards inducibility occurs in some, but not all, cells.

f2a2 Histone is a major component of chromatin representing 20% of the histones of all mouse cells tested including both inducible and non-inducible cell lines. The changes observed in f2a2 subfractions are suggestive of either (1) a chemical modification of the $f2a2_1$ fraction causing it to migrate in a different position in the gel, that is, $f2a2_2$, or (2) a change in the synthesis of the two f2a2 subtypes similar to the situation found during sea urchin development[18]. The strong association of this histone change with the ability of the cell to respond to DMSO suggests that the change opens up groups of genes which can now be induced by DMSO. Evidence from different laboratories indicates that DMSO affects both physical structure and biochemical function of chromatin[12,13]. In the Friend cell system, DMSO produces a group of changes related to erythroid maturation[6–10]. This pleiotropic response may be explained by (1) a structural change in the chromatin of the already committed erythroid cell produced by the $f2a2_2$ modification and (2) a further change in this altered chromatin by DMSO.

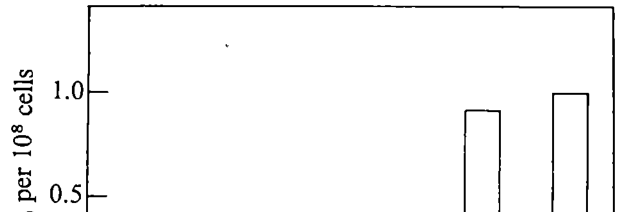

Fig. 3 Relationship of haemoglobin production to relative amounts of $f2a2_2$. After 5 d in 1.5% DMSO, cells were counted, washed twice in 0.14 M NaCl and separated into two fractions. One fraction was placed in distilled water and the cells were disrupted in 1% sodium dodecyl sulphate. Cell debris was removed by centrifugation at 1,500*g* for 10 min and the supernatant solution was read at 410 nm (refs 20 and 21). From the second fraction the histones were extracted (Fig. 1) and the amount of each f2a2 subfraction was determined.

Histones extracted from leukaemic spleens and erythroid spleens do not show the increase in $f2a2_2$ seen in DMSO-responsive Friend cell lines, although haemoglobin synthesis occurs. This may reflect the heterogeneity in the cells taken from these spleens. Studies of early erythroid cells isolated from these tissues are in progress to resolve this question. Whatever differences may exist between the control of erythroid development *in vitro* and *in vivo* seem to be circumvented by DMSO in the presence of an alteration of f2a2, since the contribution of two factors leads to apparently normal erythroid maturation[6–10].

The fact that histone f2a2 is so conserved during evolution suggests that the specific change we observe in the ratio of the f2a2 subfractions serves a purpose that enables the Friend cells to grow autonomously in tissue culture and to respond to DMSO *in vitro*.

We would like to thank D. B. Stollar, of Tufts Medical School, for his assistance with the complement fixation assay and L. Cohen and C. Alfagime, of the Institute for Cancer Research, for their helpful discussions.

DNA ligases during rat liver regeneration

DNA ligase catalyses the formation of phosphodiester bonds at single-strand breaks in double-stranded DNA[1]. Since DNA is replicated discontinuously, and radiation-induced DNA single-strand breaks are effectively repaired in both bacteria and eukaryotes, bacteria and mammalian cells will require DNA ligase function both for replication and repair of DNA[2–5]. A DNA ligase activity has also been found in and purified from mammalian cell extracts[6]. It required ATP as a cofactor and was found in highest amounts in tissues containing rapidly dividing cells. In agreement with these data it has been reported that the DNA ligase activity increased five- to tenfold in rat liver extracts during liver regeneration[7,8]. We have shown that mammalian cells contain two different DNA ligases (I and II) both of which are found in nuclei and cytoplasm, but neither of which is predominantly a mitochondrial enzyme[9,10]. Both enzymes require ATP but have different molecular weights, fractionation properties, and heat stability. Furthermore, rabbit antibodies against purified calf thymus DNA ligase I effectively inhibit DNA ligase I from calf, mouse, rabbit, and human tissues, whereas DNA ligase II from the same sources is not inhibited. It was therfore of interest to determine whether the increase in total DNA ligase activity reported to occur during liver regeneration was due to an increase in both DNA ligase I and DNA ligase II activities or due to an increase in only one of the two enzymes. Such determinations are now possible when chromatographic properties of the enzymes are known, and antibodies against DNA ligase I are available. This report shows that the level of DNA ligase I activity increases about 15-fold during rat liver regeneration, whereas the level of DNA ligase II activity remains essentially unchanged.

Male Sprague–Dawley rats (~200 g) were partially hepatectomised (to about 70%) as described previously[11]. At indicated times after hepatectomy two rats were killed, the livers immediately taken out, rinsed in ice-cold 0.25 M sucrose, rapidly frozen to −70 °C, and kept at this temperature until preparation. Cell extracts from equal amounts of liver from two rats (approximately two half livers) were prepared and purified by streptomycin treatment, ammonium sulphate fractionation (40–65% saturation), and stepwise phosphocellulose chromatography as described previously[10]. These fractionation steps were used to remove nucleases and other activities potentially interfering in the enzyme assays. Earlier experiments with calf tissue DNA ligases have not given indications that any of the two DNA ligases are selectively lost during these purification steps[10]. DNA ligases I and II were separated by hydroxyapatite chromatography: I activity was eluted with 0.14 M potassium phosphate (*p*H 7.2) and II with 0.40 M potassium phosphate[10]. Assignment of these fractions with DNA ligase I and II were verified by experiments with the anti-serum against calf thymus DNA ligase I, which inhibited more than 95% of the ligase activity in the 0.14 M eluate, whereas the activity in the 0.40-M eluate was inhibited 0–20% due to tailing of DNA ligase I during chromatography, as described previously[10]. The eluted hydroxyapatite fractions were pooled, concentrated by ammonium sulphate precipitation, redissolved, and dialysed against 0.3 M NaCl–0.05 M Tris-HCl–1 mM EDTA–1 mM dithiothreitol (*p*H 7.4) for 14–16 h before assay. DNA ligase activity was determined after preincubation of the fractions at 0 °C for 5 min with either control serum or antiserum against DNA ligase I. The ligase assay used measures the conversion of 5′-^{32}P-phosphoryl termini at single-strand breaks in double-stranded DNA to a form resistant to alkaline phosphatase[10,12].

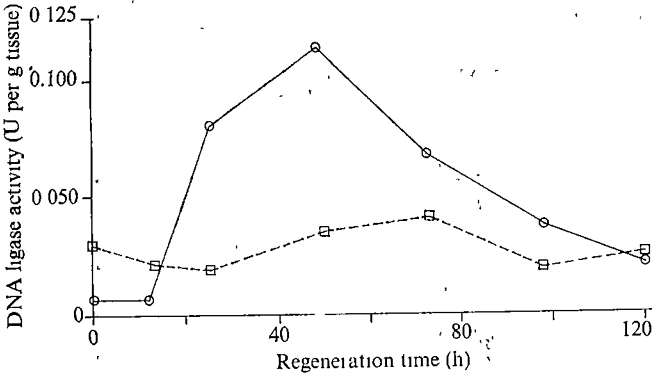

Fig. 1 Levels of activity of DNA ligases I (○) and II (□) during rat liver regeneration Each point represents duplicate experiments with several different enzyme concentrations.

The data obtained for the different time points are given in Fig. 1. Normal rat livers contain a relatively low level of DNA ligase activity, and most of this activity is due to DNA ligase II. The levels of this enzyme seem to remain essentially constant during liver regeneration as the measured variation is less than twofold. In contrast, DNA ligase I activity increases approximately 15-fold to a broad maximum at about 48 h regeneration time; and is thus the dominant DNA ligase activity in extracts from regenerating rat livers. After 5 d regeneration, the level of DNA ligase I had almost returned to the value found in normal rat liver. It is clear that the previously discovered increase in DNA ligase activity during liver regeneration[7,8] is almost entirely due to an increase in DNA ligase I. Together with our earlier published results[9,10], the present data strongly indicate that mammalian cells contain two different DNA ligases.

The isolated hydroxyapatite fractions of DNA ligases I and II from the 48-h regenerating livers were used for two additional control experiments. When separately chromatographed on Sephadex G-150 in 0.3 M NaCl–0.05 M Tris-HCl–1 mM EDTA–1 mM dithiothreitol *p*H (7.4), the ligase activity of these fractions showed identical elution properties to the corresponding calf thymus enzymes. Furthermore, when the separate enzyme fractions were heated at 45 °C for 5 min in the same buffer as that used for gel chromatography (protein concentration: 3 mg ml^{-1}), the rat DNA ligase I fraction retained more than 95% of its initial activity, whereas the rat DNA ligase II retained less than 5% of the initial activity. These data show that the rat DNA ligases are of similar heat lability and molecular weight as the corresponding calf thymus enzymes. To determine whether the apparent increase in DNA ligase I activity could be explained by the presence of DNA ligase I inhibitors in the 0-h liver fractions, or by the presence of effectors in the 48-h fractions, mixing experiments were carried out. Calf thymus DNA ligase I (1×10^{-3} U 1,000-fold purified enzyme) was separately mixed with several concentrations (0.5–3×10^{-4} U) of the 0-h or 48-h hydroxyapatite fractions of rat liver DNA ligase I. In all cases, the observed DNA ligase activity was identical (±10%) to the expected value calculated as the sum of the individual ligase activities of the mixed fractions. Thus, the 15-fold increment in DNA ligase activity during liver regeneration did not seem to be due to artefacts such as differences in interfering factors between the extracts. It is clear that whereas DNA ligase I activity in normal rat liver is low, the cells still contain detectable amounts of this enzyme. Similar control experiments with fractions containing DNA ligase II also demonstrated the absence of assay artefacts in this case. To check liver regeneration, the amount of DNA polymerase α activity was measured in the cell extracts, and was about five times higher after 24 h regeneration than in extracts from control livers, in agreement with earlier determinations[13]. Moreover, the weight of the livers successively increased during regeneration.

Regenerating liver has often been used as a system in which a population of non-dividing (G_0) cells is turned into an actively proliferating state with a high level of DNA replication. Many enzymes associated with synthesis of DNA and its precursors are known to increase during liver regeneration, but the time required for maximal induction varies considerably for the different enzymes. Moreover, in the case of multiple enzymes with similar function, the response of the individual enzyme activities to regeneration might be quite different. In the case of mammalian DNA polymerases, the DNA polymerase α activity shows a five- to sevenfold increase during rat liver regeneration[13], and DNA polymerase γ activity has also been reported to increase in cells actively synthesising DNA[14]. In contrast, the level of DNA polymerase β activity remains constant or shows only a minor increase in the same conditions[13,14]. The increase in DNA polymerase α and γ during cell proliferation in these and other systems has been considered as circumstantial evidence for their involvement in DNA replication[13,14]. The present data on DNA ligases I and II levels during liver regeneration clearly resemble the previous findings for the DNA polymerases. In this regard, note that DNA ligase I has also been found in relatively large amounts in rapidly dividing cell populations such as calf thymus and mouse ascites tumour cells, but in much lower amounts in calf liver; whereas DNA ligase II levels have shown relatively minor variations between different tissues[10]. As the levels of both DNA polymerase α and DNA polymerase γ activities increase during cell proliferation, it seems possible that DNA ligase I acts together with one or both of these enzymes in DNA replication, and that the cellular levels of that polymerase and the ligase are regulated in coordination. DNA polymerase β and DNA ligase II, neither of which show increased levels during cell proliferation, may then have functions in maintaining the integrity of DNA.

I thank Dr Tomas Lindahl for discussions, Dr Bernd Otto for carrying out the measurements of DNA polymerase α activity, and Ms Berit Sperens for assistance. This work was supported by the Swedish Natural Science Research Council, the Swedish Cancer Society and the Karolinska Institutet.

Single-stranded regions in regenerating rat liver DNA

SEVERAL groups have identified single-stranded regions in actively replicating eukaryote DNA[1–5]. We have used isopycnic caesium sulphate gradients containing silver ion, and a single-strand-specific endonuclease to determine the single strandedness of DNA from actively regenerating rat liver, and from 'control' liver of partially hepatectomised rats that had been allowed to regenerate their normal liver mass. More single-stranded DNA was observed in regenerating liver than in control livers.

One-month-old male Sprague–Dawley rats were subjected to partial hepatectomy[6]. Seven animals were killed 20.5 h later and their livers were removed. A second group of seven was housed and fed *ad libitum* for 14 d before being killed; in these conditions more than 95% of the original liver mass was restored[7]. Nuclei were isolated by the method of Blobel and Potter[8] and DNA was purified using Marmur's procedure[9].

Figure 1 shows the results of Cs_2SO_4–Ag^+ isopycnic centrifugation of DNA from the two groups of hepatectomised rats. The gradient profile of a mixture of native and heat-denatured 14-d hepatectomised rat DNA is given in Fig. 1*a*. Denaturation of DNA causes an increase in silver ion binding leading to an increase in buoyant density[10]. Denatured DNA banded with a peak density of 1.63 g cm^{-3} and native DNA banded with a peak density of 1.50 g cm^{-3}. The identities of the peaks were confirmed when native DNA was centrifuged separately (data not shown). When DNA from actively regenerating (20.5-h) liver was centrifuged in identical conditions (Fig. 1*b*), its buoyant density was greater than that of 14-d regenerating DNA by 0.09 g cm^{-3} (Fig. 1*a*). After dialysis against 0.015 M NaCl–0.0015 M sodium citrate, *p*H 7.5, the peak fraction of Fig. 1*b* had a characteristically double-stranded thermal denaturation pattern and a hyperchromicity of 37%. (It should be noted, however, that thermal denaturation patterns detect only large amounts of single-strandedness.) Thus, DNA from actively proliferating liver seems to be more single-stranded than DNA from control liver.

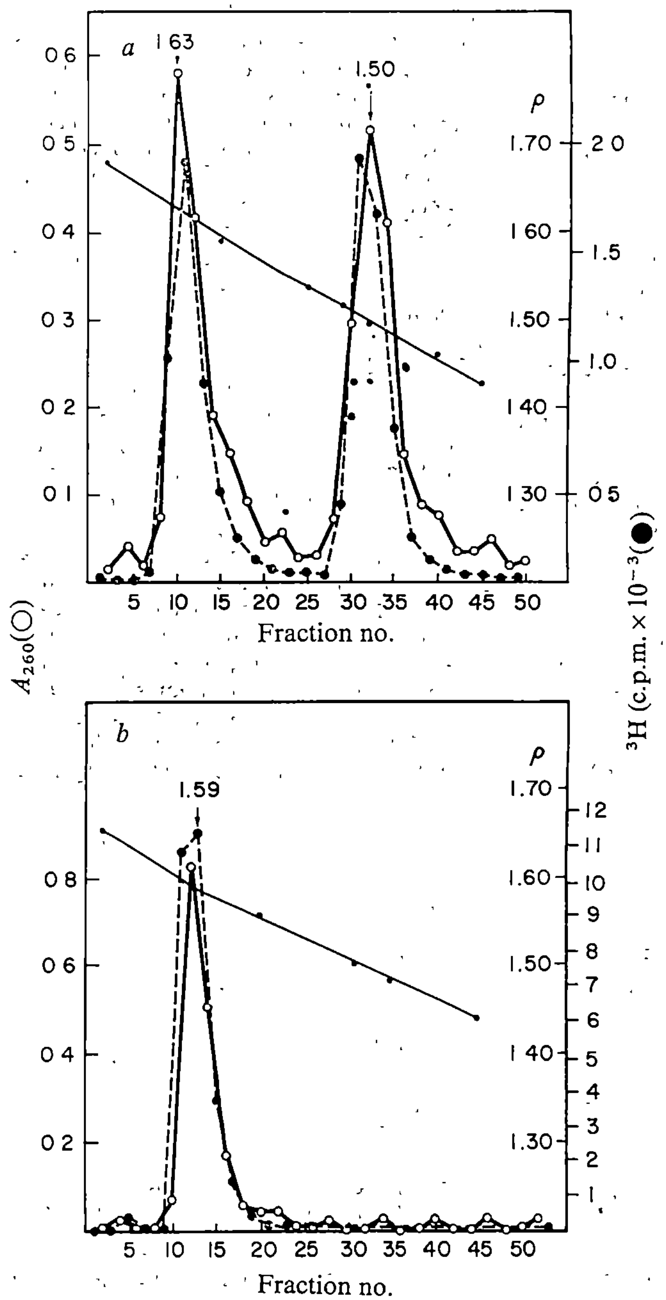

Fig. 1 Cs_2SO_4–Ag^+ isopycnic centrifugation of 20.5-h and 14-d regenerating rat liver DNA. The procedure has been described before[10]. Rats were injected 20 h after hepatectomy, through the tail vein, with ^{3}H-methyl thymidine (New England Nuclear; 50.8 Ci mmol^{-1}) at a concentration of 1 μCi per body weight. Specific activities of the 20.5-h and 14-d hepatectomised rat liver DNAs were 780 c.p.m. μg^{-1} and 127 c.p.m. μg^{-1}, respectively. DNA was dialysed sequentially against 0.1 M EDTA, *p*H 8, 0.1 M $NaClO_4$ and 0.01 M Na_2SO_4. The DNA (200 μg) was added to 6.3 g Cs_2SO_4 (Gallard–Schlesinger ultrapure) in sodium borate buffer, *p*H 9.2, to give a final concentration of 5mM $AgClO_4$ was added in drops to a final concentration of 16 μM and a molar ratio of Ag–DNA-P of 0.27. The solution was adjusted to a density of 1.5 g cm^{-3} and a final volume of 10 ml by the addition of water and/or Cs_2SO_4. Centrifugation was performed in a Beckman model L3-50 ultracentrifuge in a type 65 rotor at 20 °C for 70 h at 35,000 r.p.m. Fractions were collected from the bottom. Densities of samples of selected fractions were calculated from refractive indices determined with a Bausch and Lomb refractometer. Samples (0.1 ml) of odd-numbered fractions were applied to filter disks, dried, and washed sequentially in cold 5% trichloroacetic acid, ethanol, and ether. The radioactivity was determined in a Liquifluor–toluene cocktail with a Beckman LS-355 liquid scintillation counter at an efficiency of 54% for tritium. Even-numbered fractions were diluted with 0.5 ml of water and the A_{260} was determined with a Gilford model 2400-2 spectrophotometer. *a*, 100 μg heat-denatured DNA plus 100 μg native DNA from 14-d regenerating rat livers. *b*, 200 μg native 20.5-h regenerating rat liver DNA.

The kinetics of release of acid-soluble material from single-stranded DNA by S1 nuclease from *Aspergillus oryzae*[11] was determined using heat-denatured calf thymus DNA. After 30 min of treatment with S1 nuclease, approximately 90% of denatured DNA was rendered acid-soluble. To test for the presence of endogenous nucleases in our rat liver DNA preparations, the DNA was incubated without added enzyme. No significant release of acid-soluble material was detected.

To confirm that our S1 nuclease preparation was free of contaminating double-strand nuclease activity, a covalently closed circular DNA (R6K plasmid[12]) was examined by sedimentation in sucrose density gradients before and after treatment with S1 nuclease (data not shown). The only action observed was a slow nicking of the supercoiled covalently closed circular form. A similar slow nicking of another covalently closed circular molecule (φX174 RFI) by S1 nuclease has been reported by Godson[13]. Thus, our nuclease seems to be free of double-strand nuclease activity.

DNA from each group of rats was treated with S1 nuclease. The quantities of A_{260} U of 20.5-h and 14-d post-hepatectomy DNAs that were sensitive to S1 nuclease were 3.9% and 1.3%, respectively. Thus, DNA obtained 20.5 h after hepatectomy contained three times more single-strand nuclease-sensitive sites than DNA from 14-d regenerate livers. Since the mitotic index of cells from actively regenerating liver is about 300 times higher than that of cells from normal liver[14], our results seem to correlate with cellular replication. Our findings agree with those of Suzuki, *et al.*[15], who, using the electron microscopic immunoperoxidase method, found more single-stranded sites in DNA in nuclei from regenerating liver than in nuclei from control liver. DNA from actively replicating cells of the iris of the newt, *Triturus*, has been reported to contain more single-stranded regions than DNA from non-replicating cells[5].

In summary, there seem to be more single-stranded regions in DNA from actively dividing liver cells than in DNA from non-dividing liver cells. The physiological significance of single-stranded regions is not clear, but they are likely to be involved in DNA replication. This work was supported by grants from the National Cancer Institute and the American Cancer Society. We thank Dr Francis L. Macrina for R6K DNA.

Nalidixic acid and bacterial chromosome replication

NALIDIXIC acid (NAL) has been described as a specific inhibitor of bacterial DNA synthesis *in vivo* and *in vitro*[1–3], but its mechanism of action on susceptible bacteria remains obscure. There is no evidence to indicate that NAL can bind to DNA[3,4], and none of the enzymes known to be involved in DNA replication is affected by NAL *in vitro*[3–6]. But it is known that *nalA* mutants of *Escherichia coli* are resistant to the drug[7], as are *in vitro* DNA replicative systems derived from such mutants[3]. This suggested that a comparative study of DNA replication in *nalA* mutants and otherwise isogenic bacteria should facilitate identification of the hitherto unknown NAL target. We report here that NAL specifically arrests the later stages of chromosomal replication in bacteria sensitive to the drug.

Continuous DNA-labelling with ^{3}H-thymidine was done as before[8] using *E. coli* strains KL16 (NAL^{s}) and MH5 (a *nalA* mutant of KL16; ref. 7); in the presence and absence of the drug at 20 μg ml^{-1}. The results (Fig. 1) show that addition of NAL rapidly inhibited DNA synthesis in strain KL16 without significantly affecting that of strain MH5.

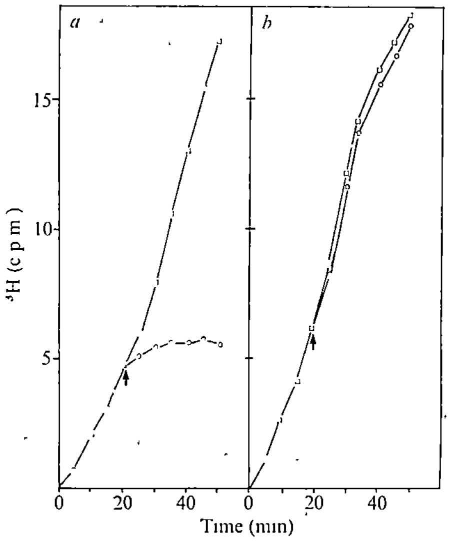

Fig. 1 Incorporation of ^{3}H-thymidine into DNA measured by continuous labelling in the presence and absence of NAL at 20 μg ml^{-1}. *a*, *E. coli* KL16; *b*, *E. coli* MH5. For both strains: □, no drug; ○, drug-treated. The arrows indicate the time of addition of NAL to 20 μg ml^{-1}. Bacteria (initially 10^{7} viable units per ml) were cultured at 30 °C in Davis and Mingioli (DM) medium containing ^{3}H-thymidine (0.1 μCi ml^{-1}) and deoxyadenosine (50 μg ml^{-1})[8]. At the times shown 1-ml samples were treated with 0 1 ml trichloroacetic acid at 0 °C and filtered through Whatman GF/C filters After washing with 1 volume of 1% trichloroacetic acid, boiling distilled water (3 volumes), 5% NaCl (1 volume) and 5% acetic acid (2 volumes), the filters were dried and radioactivity was determined by scintillation counting.

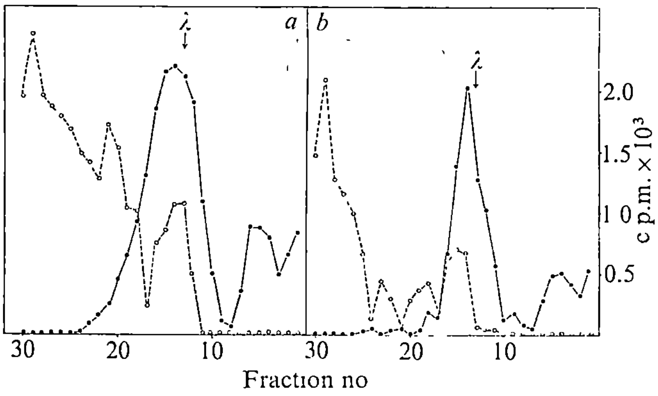
Pulse labelling[9,10], however, yielded markedly different results Using alkaline sucrose density gradient centrifugation with a 5-min pulse of ^{3}H-thymidine and a 15-min label-free chase period, DNA replication in the two strains was examined both in the absence of the drug and after 20 min of treatment with NAL (20 μg ml^{-1}). Monomeric linear ^{14}C-labelled phage λ DNA was used as a sedimentation marker throughout. In the untreated cells of strain KL16 an even distribution of single-stranded DNA fragments was observed throughout the gradient after pulse-labelling (Fig. 2*a*) During a subsequent label-free chase period all the low and most intermediate sized DNA precursors had been converted into DNA of high molecular weight. When the bacteria were treated with NAL for 20 min before a pulse label, single-stranded DNA fragments were still synthesised (Fig 2*b*). DNA of high molecular weight, however, was absent and there was an abnormal accumulation of DNA of intermediate size of about 38S. Moreover, these 38S DNA precursors could not be chased into DNA of higher molecular weight.

When the amount of pulse label incorporated into DNA

Fig. 2 DNA size distributions. *a*, Distribution of pulse-labelled (●) DNA from strain KL16 obtained by alkaline sucrose gradient centrifugation: ○, results obtained after a similar pulse followed by a 15 min label-free chase period. *b*, Distribution of pulse-labelled (●) DNA from strain KL16 obtained by alkaline sucrose gradient centrifugation of a culture treated with NAL (20 μg ml^{-1}) for 20 min before isolation: ○, results obtained after a similar pulse followed by a 15-min label-free chase period in the presence of NAL. (Fractions are numbered from the top of the gradient.) Bacteria (approximately 10^7 viable units per ml) were inoculated into 10 ml DM medium at 30 °C. Thymidine and deoxyadenosine were added to give final concentrations of 200 μCi ml^{-1} and 50 μg ml^{-1}, respectively. After 5 min, half the culture was membrane-filtered and washed with 2 volumes of chilled medium lacking glucose, deoxyadenosine and thymidine (pulse). The other half of the culture was also filtered after 5 min but was washed with 2 volumes of DM medium lacking deoxyadenosine and thymidine at 30 °C. This filter membrane was immersed in 5 ml of fresh DM medium lacking only deoxyadenosine and thymidine at 30 °C, the cells were detached from it by agitation and the membrane discarded. After 15 min at 30 °C the cells were collected again by membrane filtration and washed with 2 volumes of chilled medium lacking glucose, deoxyadenosine and thymidine (pulse chase). The two membranes carrying pulsed and pulse-chased bacteria were resuspended in 1 volume of DM medium lacking glucose, deoxyadenosine and thymidine and the bacteria were detached by agitation. The membranes were discarded and the suspension was centrifuged at 3,000*g* for 10 min. The pellets were each resuspended in 0.6 ml of 0.1 M NaOH containing 10 mM EDTA. λ phage DNA labelled with ^{14}C was added as a 34S sedimentation marker and the mixture was incubated at 37 °C for 1 h. After clarification at 3,000*g* for 10 min, the upper 0.4 ml of each supernatant was layered on 13 ml sucrose gradients (5–20%) of 0.9 M NaCl, 0.1 M, NaOH and 2 mM EDTA and centrifuged at 38,000 r.p.m. in an S40/135 rotor for 3 h at 20 °C. Thirty fractions were then collected from the top of the gradient and 1 ml of cold 10% trichloroacetic acid added to each. Precipitates were collected on Whatman GF/C filter disks and washed with 5×10 ml portions of cold 1 M HCl. The filters were dried and radioactivity determined by scintillation counting.



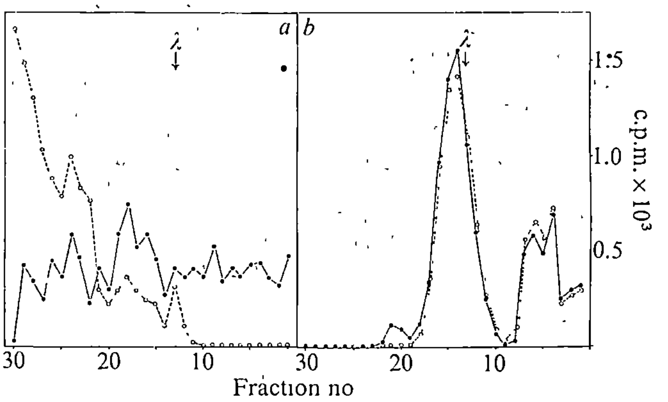


Fig. 3 DNA size distributions. *a*, Distribution of pulse-labelled DNA (●) from strain MH5 obtained by alkaline sucrose density gradient centrifugation; ○, results obtained after a similar pulse followed by a 15 min label-free chase period *b*: ●, DNA from strain MH5 obtained by alkaline sucrose density gradient centrifugation of a culture treated with NAL (20 μg ml^{-1}) for 20 min before pulse labelling; ○, results obtained after a similar pulse followed by a 15-min label-free chase period in the presence of NAL. (Fractions numbered from the top of the gradient.) The experimental details were the same as those described in the legend to Fig. 2.

in the presence and absence of NAL was calculated, the result was surprising. NAL (20 μg ml^{-1}) inhibited DNA synthesis by only 14% after 20 min of treatment, whereas the continuous label study had indicated that DNA synthesis was inhibited by about 80% in identical conditions.

Examination of the DNA replication of the *nalA* mutant strain MH5 by pulse labelling showed that this organism accumulated 38S single-stranded DNA fragments even in the absence of the drug (Fig. 3*a*) During the chase period these precursors were converted slowly into DNA of high molecular weight. When the experiment was repeated with strain MH5 treated with NAL (20 μg ml^{-1}) for 20 min before a pulse label, the accumulation of DNA precursors and their conversion into DNA of high molecular weight proceeded relatively unimpaired (Fig. 3*b*).

Thus the *nalA* mutation slows the joining of 38S DNA precursors and sensitive bacteria treated with NAL are inhibited at the same step, in that they accumulate 38S DNA fragments which cannot be converted into DNA of higher molecular weight. Thus it seems that the *nalA* gene product has a unique role in the sealing of 38S single-stranded DNA precursors, which seems to be a hitherto unknown vital step in the replication of the bacterial chromosome.

There remains the apparent discrepancy between the continuous and pulse labelling results with strain KL16. When the sequential events of DNA replication are considered, however, the two results can be reconciled as follows.

In bacteria sensitive to NAL, exogenous ^{3}H-thymidine is incorporated into 10S Okazaki fragments[11]. These are joined by DNA ligase into longer single-stranded DNA, of molecular weight 38S, which in turn are converted into full-sized daughter molecules. This last step seems to be governed by the action of the *nalA* gene product. When sensitive bacteria are treated with NAL it is only this step that is inhibited (Fig. 2) so that gaps remain between each 38S single-stranded DNA precursor. Thus NAL does not inhibit the incorporation of ^{3}H-thymidine into trichloroacetic acid insoluble single-stranded DNA of low or intermediate molecular weight, as measured by pulse labelling. In other words, NAL does not inhibit DNA synthesis. But, the newly synthesised single-stranded DNA precursors, by virtue of the unsealed gaps, are most probably metabolically unstable, as they will be substrates for exonuclease action. Such degradation, which has been described during NAL treatment of *Bacillus subtilis*[14], would return the ^{3}H-label to the intracellular thymine pool from where it would be recycled into Okazaki fragments. Thus net DNA synthesis would cease because of the transience of the newly synthesised DNA intermediates, and this is the result we obtained with continuous labelling of DNA. Experimental support for these views is given by the finding that competent RNA and protein syntheses are essential prerequisites for both exonuclease action and the bactericidal action of NAL[8,13], and thus our results seem not only to provide evidence about the nature of the target site for NAL, but also to indicate how the drug kills bacteria.

π Turn is a conformational pattern in RNA loops and bends

A PATTERN has been found in the structure of transfer RNA by which a polynucleotide chain can make an abrupt change in direction so as to make a sharp cornered loop or a sharp bend.

Nucleotide sequences[1] of transfer RNAs (tRNAs), ribosomal RNAs (rRNAs) and phage RNAs suggest that they can be represented as a series of double-stranded helices with loops separated by short stretches of single-stranded RNA. The single-stranded loops and short stretches have been implicated as the recognition sites for proteins or other nucleic acids.

The three-dimensional structure of yeast tRNA^{Phe} determined by X-ray crystallography provides conformational information about such single-stranded regions. The backbone structure of this tRNA molecule revealed that the loops have sharp corners[2] rather than being smooth. This feature was verified in detail at 3-Å resolution as well as at higher resolution for the same tRNA in two different crystalline lattices[3–7]. Examination of the TψC and the anticodon loops, both with seven nucleotides, shows that the way the backbone makes a sharp turn is the same for both loops, suggesting that this is a pattern of forming a sharp cornered loop (Fig. 1). The reversing of

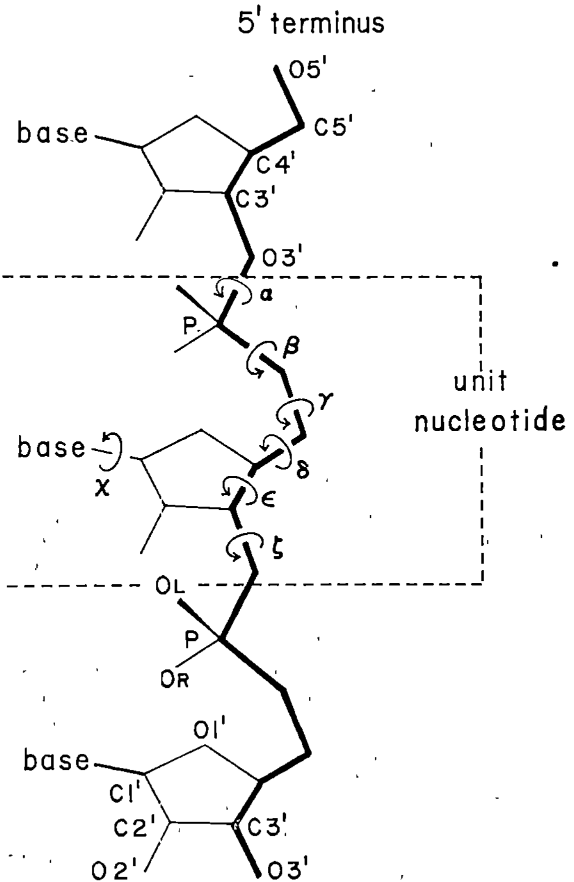

Fig. 2 The nomenclature of torsional bonds used here is a modification from that suggested in ref. 9 to accommodate all the torsional angles in one 'unit nucleotide'.

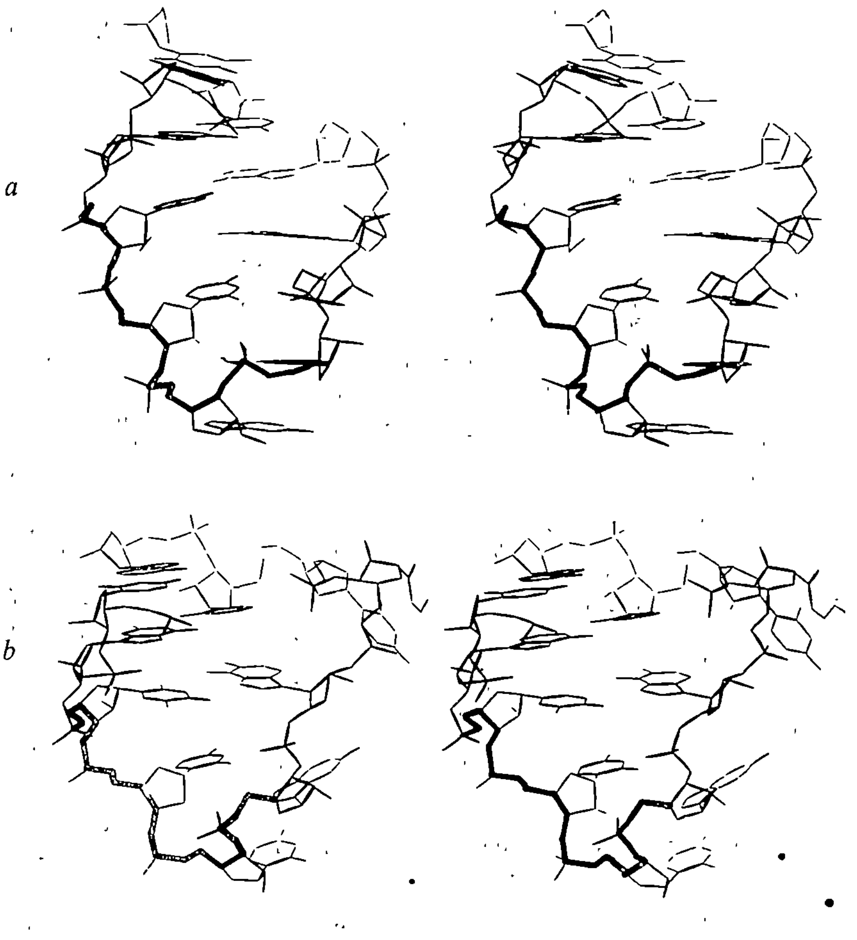

Fig. 1 Stereo view of the anticodon loop (*a*) and the TψC loop (*b*) of yeast tRNA^{Phe} At the top of each figure are two base pairs just before the loop. The 5′ end is at the upper left and the 3′ end at the upper right. The π turn occurs at the phosphodiester link between the bottom nucleoside and that at the 5′ side of it. These computer drawings are based on the atomic coordinates of this tRNA structure in the orthorhombic crystal form[6] The side chain tail of the Y base has been omitted from (*a*) for clarity, and the backbone of the 5′ half of the loops are darkened.

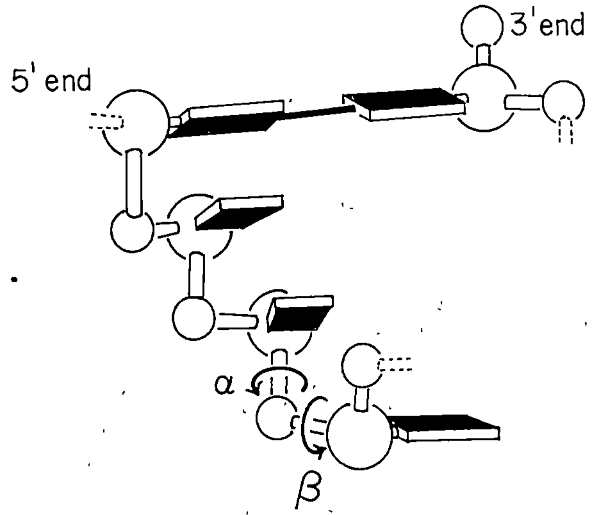

Fig. 3 Schematic drawing of the common portion of Fig. 1*a* and *b*. The circular arrows indicate two bonds involved in π turn to reverse the direction of the backbone from a helical conformation.

the direction of the backbone chain from the helical conformation occurs, in both cases, within just one phosphodiester link by rotating primarily around O3′–P and P–O5′ (torsion angles α and β, see Fig. 2) of the third nucleotide from the 5′ end of the loop. These two phosphoester bonds were initially pointed out to be the two least constrained backbone torsion angles[8]. This is shown schematically in Fig. 3. Besides these two examples there are several more sharp turns formed by similar rotations around the α and β in the DHU loop, the variable loop, between the helices and in the TψC loop.

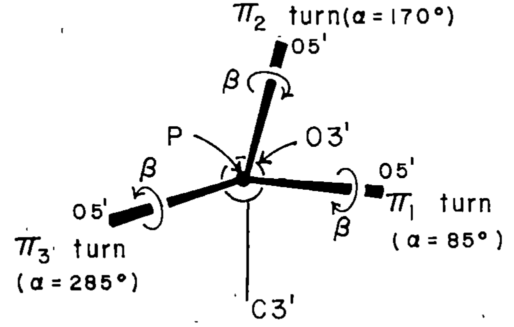

Fig. 4 Three families of π turns, as distinguished by their α angles, are viewed along the P–O3′ bond. The sharpness of the turn is dictated by how much the β angle deviates from a helical conformation.

For convenience, we define the π turn to describe a set of sharp turns in a polynucleotide chain, all due to the rotation around two adjacent phosphoester bonds, causing changes in the direction of the backbone chain. There are three possible families of π turns, depending on the orientation of the P–O5′ bond with respect to the C3′–O3′ bond, that is the torsion angle α, as shown in Fig. 4: called π_1, π_2 and π_3 turns with α values near 85°, 170° and 285° respectively. The three representative α angles chosen here are based on the observed values in crystal structures of several dinucleoside phosphates[9]. The most common turn found in yeast tRNA^{Phe} is the π_3 turn. This is observed in the phosphodiester links between residues 9 and 10, 17 and 18, 33 and 34, 46 and 47 and 55 and 56. The sharpness of the turn depends on how much the β angle deviates from a helical conformation (near 290°) (ref. 9). The other two classes of π turns are also found in this tRNA structure; for example, π_1 turn between 47 and 48; π_2-turn between 15 and 16. There are several more π turns in the tRNA structure which are uncertain, at the current stage of refinement, to assign a specific class.

The π_1 turn has been observed in the crystal structures of uridylyl 3′,5′-adenosine phosphate, UpA[10,11], ApApA[12] and ApU·9-aminoacridine[13] where two oppositely oriented riboses are connected by one phosphodiester linkage.

Thus, it seems that the π turn provides a simple, general pattern by which a polynucleotide chain makes a sharp turn, either to form a loop or to change the direction of the chain flow. Such a sharp cornered loop or turn produces a small compact protrusion, which could fit into a depression or groove on the surface of a protein with which it interacts.

Systematic nomenclature for the RNA polymerase genes of prokaryotes

THE DNA-dependent RNA polymerase of *Escherichia coli* (EC 2.7.7.6) consists of at least four distinct polypeptide subunits; *α*, *β*, *β′* and *σ* (ref. 1). Other subunits have been reported (for example, *ω* (ref. 1) and *σ′* (ref. 2)), but their importance in transcription remains uncertain. Many prokaryotes are known to contain RNA polymerases of closely similar subunit composition, including a wide range of bacteria[3] and a blue-green alga[4]. Until recently, only the structural gene for *β* had been identified in *E. coli*[5]. It is located[6–10] at 88.5 minutes on the recalibrated genetic map[11], and is characterised principally by mutations conferring resistance to specific drugs. The *β*-gene has thus acquired several synonyms derived from the mutant phenotypes, including *rif* (for resistance to rifampicin)[8], *stv* (for streptovaricin)[9], and *stl* (for streptolydigin)[10,14]. More recently the structural gene for the *β′* subunit has been characterised in *E. coli*; it is adjacent to the *β* gene[13], and in the same operon[14–16]. Finally, the gene coding for *α* has been located at 72 minutes[11,17–19]. We now propose a systematic nomenclature for the RNA polymerase genes of *E. coli*, which could equally be applied to other prokaryotic organisms. We have consulted other workers in the field, whose comments have been assimilated into our proposal. The scheme, which is in line with the recommendations of Demerec *et al.*[20], is as follows.

(1) The symbol *rpo* should be applied to the structural genes coding for RNA polymerase subunits, and to their regulatory genes and sites. (The symbol *rna*, proposed in 1968 (ref. 7), has not come into general use[11].)

(2) The genes for the *α*, *β* and *β′* subunits should be called *rpoA*, *rpoB* and *rpoC*, respectively. We suggest that

the gene for σ be *rpoD*, and that any further structural genes should continue the alphabetical sequence.

(3) The promoter for the *rpoB,C* operon[14] should be designated *rpoP*. We suggest that further regulatory genes and sites, controlling *rpo* structural genes, should continue the alphabet from *rpoO*.

(4). All *rpo* mutations should be identified by the gene letter, followed by a number. We strongly support the principle[20] that allele designations should not attempt to convey phenotypic information.

Table 1 lists some well-characterised mutations established in the literature, together with their agreed new names. We will gladly coordinate the future naming of mutations.

Table 1 lists some well-characterised mutations established *E.coli*[11].

We thank many colleagues for support and help in the shaping of this nomenclature, particularly the following: S J. Austin, B J. Bachmann, D. Boyd, R. R. Burgess, R. Calendar, I. V. Claeys, R. Doi, H. Echols, G. R. Hartmann, A. Heil, A. Ishihama, R. B. Khesin, J. B. Kirschbaum, J.-P. Lecocq, R. Losick, B. Low, H. Matzura, D. McConnell, J. H. Miller, B. Molholt, M. Nomura, M. Oeschger, P. Palm, L G. Silvestri, A. L. Sonenshein, W. Szybalski, A. L. Taylor, I. Tittawella, A. Travers, A. Wright, T. Yura and W. Zillig. We thank the MRC for project and programme grant support.

Enthalpy–entropy compensation of oxamate binding by homologous lactate dehydrogenases

STUDIES[1,2] of the amino acid sequence and crystal structure of M_4 lactate dehydrogenase (EC 1.1.1.27) indicate that all binding interactions are of the weak, non-covalent type (proceeding with only minor free-energy changes). Because critical regions of the substrate and coenzyme-binding site seem highly conserved[3], and because non-covalent interactions are highly, if differentially, sensitive to the physical environment[4], we wondered how organisms living in widely different temperatures and pressures stabilise enzyme–ligand interactions. We have therefore compared pyruvate binding site functions of lactate dehydrogenases obtained from organisms living in different temperatures and pressures. We used a placental mammal, the ox, with a cell temperature of 37 °C; a marsupial, the possum (*Trichosurus vulpecula*), with an average cell temperature of 36 °C (ref. 5), two monotremes, the platypus (*Ornithorhynchus anatinus*), with a cell temperature of about 31 °C (ref. 6), and the echidna (*Tachyglossus aculeatus*), with a body temperature of 23–32 °C (ref. 7); the goanna (*Varanus gouldi*), an Australian lizard with a cell temperature ranging from about 20 up to nearly 40 °C (ref. 8); the Pacific coast dogfish (*Squalus acanthias*), with an average body temperature of about 15 °C; an intertidal sculpin (*Oligocottus maculosus*), living in varying temperatures between about 5 and 15 °C, and an abyssal teleost fish, *Antimora rostrata*, with a highly constant body temperature of 2–3 °C. All these, except the dogfish and *Antimora*, can be viewed as species adapted to 1 atm; by contrast the abyssal species must be able to tolerate pressures of up to several hundred atmospheres, while the dogfish may encounter pressures from 1 to about 100 atm (N. J. Wilimovsky, personal communication). We found that adjustments in enthalpic and entropic contributions to lactate dehydrogenase binding allowed each homologue to bind ligand with similar avidity at its respective "normal" temperature and pressure.

M_4 lactate dehydrogenase was isolated from skeletal muscle of each species, and in all but the dogfish and sculpin, was purified to homogeneity (thrice crystallised) by standard purification procedures as before[9]. Dogfish and sculpin enzymes were purified by affinity chromatography, using oxamate covalently linked to Sepharose B as described elsewhere[10]. Enzyme activity was assayed by following the change in A_{340} due to NADH oxidation in a Unicam SP 1800 recording spectrophotometer. Cuvette temperatures were kept constant (±0.1 °C) with a Lauda constant temperature bath and circulator. To study the effects of pressure, we used a high pressure cell of 1-cm light path, with sapphire windows, installed into a Unicam SP 1800 spectrophotometer, as previously described[11].

An indication of how the substrate-binding site is adjusted with respect to the environment can be obtained from studies of oxamate inhibition of the enzyme. Oxamate, isoelectronic and isosteric with pyruvate, is considered a perfect structural analogue of the substrate[2]. During oxamate or pyruvate binding, a negative charge must be neutralised, and the overall process should be favoured by low temperature and low pressure[4]. If that were simply the case, then the lower the temperature, the higher the enzyme affinity for oxamate, and the enzyme from a low temperature organism (such as *Antimora*) would be expected to have a much higher affinity at its biological temperature than would a homologue in a high temperature organism. This situation was not observed. Although the overall effect of temperature on the K_i for oxamate is qualitatively similar, the position of each curve on the temperature axis

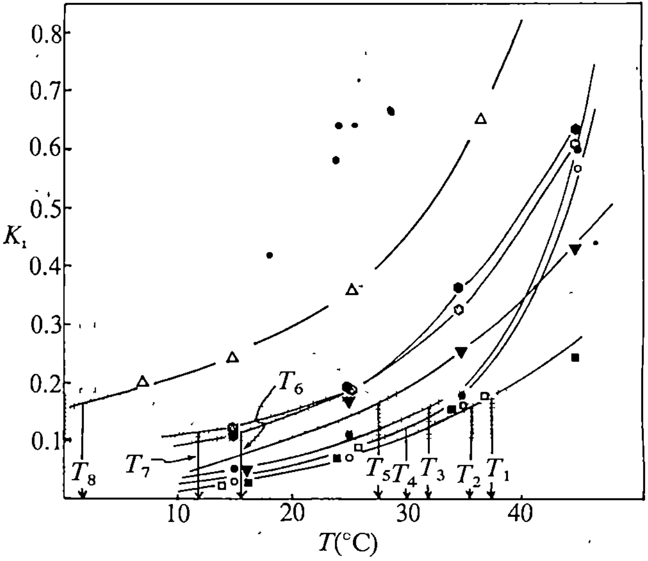

Fig. 1 A plot of the K_i for oxamate against temperature in °C for M_4 lactate dehydrogenases from eight vertebrate species. Arrows from each curve refer to the approximate body temperature in each case. T_1 refers to the ox; T_2, the possum; T_3, the platypus; T_4, the goanna; T_5, the echidna; T_6, the dogfish; T_7, the sculpin; T_8, *Antimora*. The K_i for oxamate was determined at *p*H 7.5, 100 mM Tris-HCl buffer, 25 °C, at minimally two concentrations of pyruvate, between 0.25 mM and 1 mM, and at 0.1 mM NADH. Total volume was 1 ml. Pressure was constant at 1 atm. K_i values (mM) are accurate to within ±10%. Each K_i value represents an average of three determinations from Dixon plots of 1/velocity against oxamate concentration.

Table 1 Thermodynamic parameters for association of oxamate and binary lactate dehydrogenase–NADH complexes for M_4 forms of the enzyme from species adapted to different temperatures and pressures

Enzyme source	Average biological temperature (°C)	ΔG^0 (kcalorie mol^{-1})	ΔH^0 (kcalorie mol^{-1})	ΔS^0 (calorie mol^{-1} K^{-1})	ΔV^0 (ml mol^{-1})
Ox	37	−5.7	−15.4	−32.3	36
Possum	36	−5.7	−15.2	−31.9	Unknown
Platypus	31	−5.4	−14.5	−30.5	Unknown
Goanna	20–40	−5.6	−14.5	−29.9	Unknown
Echidna	23–32	−5.2	−14.0	−29.5	Unknown
Dogfish	15	−5.1	−11.0	−19.8	5.4
Sculpin	5–15	−5.1	−8.2	−11.1	10.0
Antimora	2	−4.7	−6.1	−4.9	0

K_i values from which these data are calculated are reproducible to within ±10%. Values for ΔG^0, ΔS^0 and ΔV are calculated for data obtained at 298 K.

roughly correlates with the temperature in which each enzyme homologue normally functions (Fig. 1). In each case the affinity of the binary complex for oxamate is similar at each biological temperature (although Fig. 1 shows that at any given temperature enzymes adapted to high temperatures bind oxamate more tightly than do their homologues in organisms adapted to the cold).

Similar observations have been made for the apparent Michaelis constant for pyruvate[12]. These and our own studies imply some selective advantage if, in each species, these enzymes have a particular range of substrate affinity. Atkinson has argued persuasively that an enzyme's affinity for its substrates is designed by natural selection for optimal function within the *in vivo* concentration range through which the substrates fluctuate[13]; since pyruvate concentrations are likely to be similar in muscles of different vertebrates, similar binding ability at each respective biological temperature should perhaps be expected. Be that as it may, the question remains as to how such fine thermal adaptation of lactate dehydrogenase-binding function is achieved, particularly with a ligand as apparently simple as oxamate.

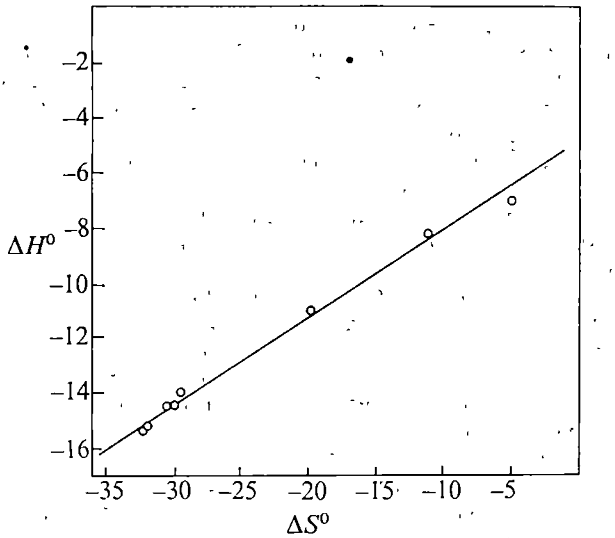

Fig. 2 A plot of $\triangle H^0$ against $\triangle S^0$ associated with oxamate-binding by the binary NADH–enzyme complex for lactate dehydrogenases isolated from vertebrate species adapted to different physical environments. The enthalpy change is in calorie mol^{-1} while the entropy change is in calorie mol^{-1} K^{-1}. The data for this plot are calculated from K_i values that are reproducible to within ±10%

One possible mechanism would involve structural adjustments at the substrate binding site *per se* so as to 'optimise' binding at different biological temperatures. Although this may be the simplest hypothesis to fit the data, current evidence indicates that critical regions of the enzyme-binding sites are highly conserved[1–3]. Therefore, we tentatively reject the hypothesis.

A second basis for this rejection perhaps is to be found in a careful analysis of the thermodynamic parameters for association of oxamate and the binary complex. Table 1 shows that the lower the biological temperature of normal function, the lower the enthalpy and entropy changes occurring during oxamate binding. Although the differences between some of the enzyme homologues are small, at the extremes of the spectrum obtained the differences are impressive: the values for ΔH^0 for oxamate binding by the possum or ox homologues are nearly 1.5 times the ΔH^0 for the dogfish enzyme and are 2.5 times the ΔH^0 for the *Antimora* M_4 enzyme. The quantitative relationship between ΔH^0 and ΔS^0 for oxamate binding by the different lactate dehydrogenases (Fig. 2) seems to be an example of "enthalpy–entropy compensation". The slope of the plot in Fig. 2 corresponds to a "compensation temperature" of about 325 K, and is similar to that obtained for ADP binding by glutamate dehydrogenase[14] and for activation parameters for vertebrate lactate dehydrogenases[15,16]. The compensation temperature range, 250–325 K, is observed so frequently that some workers believe the phenomenon to be a consequence of the properties of water as a solvent[17,18]. In general, the more water that must be removed from the substrate or from the enzyme, the higher the enthalpy and entropy changes during formation of an enzyme–substrate complex. That some such effects contribute to the thermodynamics of coenzyme and substrate binding by lactate dehydrogenases is supported by several observations. First, in the ternary complex, the position of a collapsed loop excludes bulk water from the active site, while in the apoenzyme it extends well into the solvent[1]. In this sense at least water must be removed from the enzyme during stabilisation of the ternary complex. Second, water must also be removed from the coenzyme during binding because both negative charges on the pyrophosphate are solvated in solution, but only one is solvated in the ternary complex[1,2]. Third, the degree of surface hydration of the apoenzyme compared with the ternary complex almost certainly differs significantly, although structural studies of lactate dehydrogenases have not quantified this characteristic. Fourth, enzyme–water interactions seem to vary between species, with homologues from cold-adapted species tending to have notably oily surfaces, a characteristic observed for both pyruvate kinases and glyceraldehyde-3-phosphate dehydrogenase (G. N. Somero, personal communication). Thus there seems ample possibility to adjust the thermal dependence of enzyme–ligand binding by adjusting the energetic contributions of solvation effects anywhere in the enzyme structure.

If that were true in our case, volume changes associated with oxamate-binding by lactate dehydrogenase homologues should also vary in a regular manner, the larger the ΔH^0 and ΔS^0, the larger the expected volume change (ΔV) (ref. 17). At least in a qualitative sense, this prediction is realised in preliminary studies of total volume changes during oxamate binding. Thus the expected volume increase, associated with charge neutralisation[4], appears with M_4 homologues from high cell temperature organisms[19]. In contrast, oxamate binding by the piscian binary complexes proceeds with a greatly reduced volume change (Table 1); with *Antimora* enzyme the ΔV is so close to zero it cannot be measured accurately by the techniques used. These studies are in progress and will be published in detail elsewhere. In these cases the simplest interpretation is that the positive ΔV occurring on charge neutralisation of oxamate is at least partially compensated (or accommodated) by a negative volume change of similar magnitude, but mediated by changes in the degree to which water can orient around water-density-modifying groups such as carboxylates, peptide linkages, or non-polar amino acid residues. In consequence, the total ΔV is lower than in the ox homologue. As with activation parameters[20], nothing need be assumed about where in the enzyme structure these events occur, although they probably occur somewhere removed from critical interacting regions of the substrate-binding site *per se*.

This work was supported by a grant (P.W.H.) from the National Research Council of Canada. We thank Dr Paul Dreizen for the *Antimora*.

Possible Gibbs–Donnan mechanism for cation uptake

MANY freshwater animals take up metal ions from solution in the surrounding water, often by active transport against a concentration gradient. The uptake of ions would be helped, and their loss opposed, by any means which increases the electrochemical potential of the ions in question in the external medium. One such means would be for the animal to secrete into the water a cationic substance to which the skin is not permeable; this would set up a Gibbs–Donnan effect (whereby an unequal distribution of diffusible ions is established at equilibrium on the two sides of a membrane if one side contains a non-diffusible ion) on the ions which are to be absorbed. The presence of such a mechanism in nature would be evident from the accumulation in the growth medium of cationic substances whose effect on the uptake of metals could be demonstrated experimentally.

For instance, the pulmonate snail *Biomphalaria glabrata* was shown by Thomas *et al.*[1,2] to secrete a substance which might act this way. The growth of the snails in these experiments was on the whole limited by the amount of calcium which could be absorbed, but the snails' secretion increased their growth rate and lowered the minimum concentration from which net uptake of calcium could be achieved. When the substance was allowed to accumulate in a limited volume of water (< 200 ml) for 3 d, the calcium concentration was reduced by the snails' uptake to ~ 2.5×10^{-5} M. But when the secretion was prevented from accumulating by continuous replacement of the medium, net uptake was not possible from solutions $\lesssim 2.5\times10^{-4}$ M. Addition of the partially purified secretion of other snails to the continuously replenished medium lowered the limiting calcium concentration from which net uptake was possible.

This model implies that the secretion of *B. glabrata* could increase the electrochemical potential of calcium tenfold. It is possible to calculate the effective concentration of non-permeant cations required to produce this effect, assuming that no other cations are present in significant amount. We can treat the system as though Ca^{2+} were partitioned at equilibrium between two compartments separated by a membrane permeable only to Ca^{2+} and to a common anion such as HCO_3^-. The molar calcium concentration in the compartment from which the non-permeant cation is absent (representing the interior of the snail) would then be $m'_{Ca} = 2.5\times10^{-4}$ and in the compartment where the non-permeant cation is present (representing the exterior medium) the calcium concentration is $m_{Ca} = 2.5\times10^{-5}$. If the substance in question has molecular charge z, the molar concentration, m_p, required will be given by the Gibbs–Donnan equation

$$\gamma_\pm{}^3 m_{Ca}(2m_{Ca}+zm_p)^2 = 4\gamma_\pm'^3 m'_{Ca}{}^3$$

where $\gamma_\pm$, $\gamma_\pm'$ are the activity coefficients of the calcium salt in the compartments with and without the non-permeant cation, respectively. Substituting the calcium concentrations given above, and assuming the activity coefficients equal, we obtain the value $zm_p = 1.6\times10^{-3}$, which seems reasonable.

The Gibbs–Donnan effect will operate on all permeant cations, to an extent depending on their relative concentrations and their valence. (There is more effect on multivalent than on univalent ions.) The presence of an excessive concentration of another permeant ion such as Na^+ would reduce the enhancement of the electrochemical potential of Ca^{2+}. Other things being equal, the uptake of permeant cations would be favoured in approximate proportion to their external concentrations. Other non-permeant ions would enhance or reduce the Gibbs–Donnan effect depending on their concentrations inside and outside the animal and on their net molecular charges.

Apart from the identification of cationic macromolecular substances in the secretions of freshwater animals, this model could be confirmed by reproducing the Gibbs–Donnan effect with cationic polymers such as diethylaminoethyl dextran or polylysine. The presence of these in the water at quite modest concentrations ought to assist the uptake of calcium and stimulate the growth of animals as does the substance studied by Thomas.

It is not to be expected that such a mechanism would be useful to all freshwater animals, but only to those living in limited volumes of still water in which the hypothetical substances could accumulate. Because the mechanism would act equally well to retard loss as to promote uptake of ions, it would be of greater value to animals vulnerable to such loss; for example, it would be more likely to occur among gastropods, which are liable to dissolution of the shell, than among crustaceans, whose calcareous structures are protected by an impermeable cuticle.

I am indebted to Dr A. G. Ogston for his suggestions and criticisms.

Evidence for two sodium sites on the external aspect of Na–K pump in human erythrocytes

THE Na–K pump, which actively transports Na outward and K inward, is inhibited by external Na in human erythrocytes. This inhibition has been interpreted as being either "dead end" at one of the two putative external K sites[1], or as allosteric, occurring at a third external site on the pump[2]. Both of these models assume that occupation of the pump by a single external sodium ion is sufficient to inhibit the pump. In the "dead end" model, occupation of one of the K pump sites by Na inhibits pump turnover[1]; in the allosteric model, occupation of the external sodium site decreases the affinity of the K pump sites for K, but does not inhibit K translocation once the K sites have been occupied.

The experiments which led to these models have been done at relatively low external K concentrations, [K]$_0$, well below 1.5 mM, the [K]$_0$ at half-maximal pump flux in high Na solutions[3]. When inhibition by Na of ouabain-sensitive K influx, $^1M_K{}^P$, was determined in solutions containing 2 mM [K]$_0$, results such as those in Fig. 1 were obtained. The results, presented as a Dixon plot[7] ($1/{}^1M_K{}^P$ against [Na]$_0$), fit a parabola, suggesting that two external sites must be occupied for Na to inhibit ouabain-sensitive K influx at the [K]$_0$ used. These results contrast with those obtained by Cavieres and Ellory[2] at lower [K]$_0$. Dixon plots of their data gave straight lines for K concentrations between 0.1 and 0.35 mM, and hyperbolae for concentrations less than 0.1 mM. The difference in the results at 2 mM [K]$_0$ compared with lower [K]$_0$s might be considered in terms of the relative affinities of the two sodium sites depending on whether one K ion or two occupy the external aspect of the pump. The form XK may have such a high affinity for Na at the first Na site that the effect of occupation of this site is not seen at the lower [K]$_0$s. This would be analogous to measuring K activation of the pump in Na-free solutions where the curve appears hyperbolic unless extremely low [K]$_0$s are used, where a slight sigmoidicity may become apparent. In this scheme the form KXK would have a lower affinity for Na than XK and the occupation of both Na sites would be demonstrable kinetically at a higher [K]$_0$.

Another useful way of examining extracellular Na sites on the pump is to look at the effects of [Na]$_0$ on the rate of ouabain binding. External Na increases the rate of ouabain binding to the pump, whereas external K inhibits it. The effect of Na has been attributed both to a direct action, independent of K[8], and to an action limited to restricting access of K^+ ions from the sites at which they inhibit ouabain binding[1]. In the experiment shown in Fig. 2, we altered the rate of ouabain binding (shown as the rate constant of binding), but not the K pump rate, by increasing [Na]$_0$ in a solution in which [K]$_0$ was sufficient to saturate the pump at all Na concentrations used. Thus, increasing [Na]$_0$ caused no inhibition of $^1M_K{}^P$, but the rate of ouabain binding increased fourfold. This shows that Na may occupy at least one external site without inhibiting the pump, and supports a configuration of the external aspect of the pump, $_KX_K{}^{Na}$, suggested by Cavieres and Ellory[2]. Figure 1, however, demonstrates that at least two external sites must be occupied by Na to obtain inhibition at 2 mM [K]$_0$. In low [K]$_0$ and saturating [Na]$_0$, one would expect

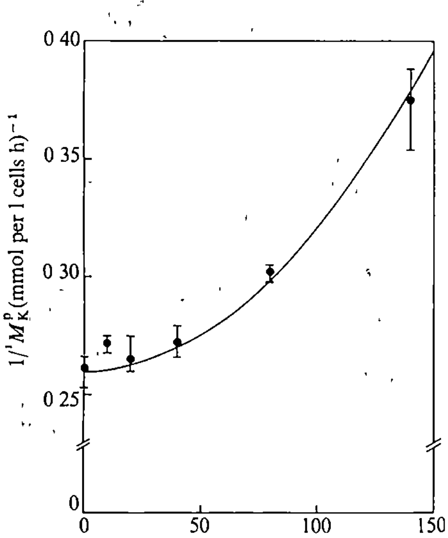

Fig. 1 Inhibition of ouabain-sensitive K influx by external Na in human red cells. Cellular cation concentrations were altered by reversibly increasing cation permeability using nystatin[4], so that [Na]$_i$ = 88 mmol per l cells and [K]$_i$ = 8 mmol per l. Unidirectional K influxes were measured using ^{42}K as before[5] in a solution containing (mM): KCl, 2; choline Cl+NaCl, 148; glucose, 5; Tris-HCl, 10 (*p*H 7.5). The cells were exposed to ^{42}K for 30 min. The maximum difference in [K]$_i$s in aliquots of cells at the various [Na]$_0$s, measured after incubation in ^{42}K, was 0.9 mmol l^{-1}. The resultant differences in $^1M_K{}^P$ due to stimulation by [K]$_i$ would be of the order of 5% (ref. 6). Ouabain-sensitive fluxes were determined after preincubation of cells in 10^{-3} M ouabain for 10 min at 37 °C in K-free media. Results are plotted as the reciprocal of the pump influx, $1/{}^1M_K{}^P$, against external Na concentration, [Na]$_0$. The curve was drawn from the equation, $1/{}^1M_K{}^P = 0.26+(6.0\times10^{-6})\,[\mathrm{Na}]_0{}^2$. The points represent means of triplicate determinations. The maximum range of values about a mean was 3.9% of the mean, and the average range was 2.4%. Similar results were obtained in another comparable experiment.

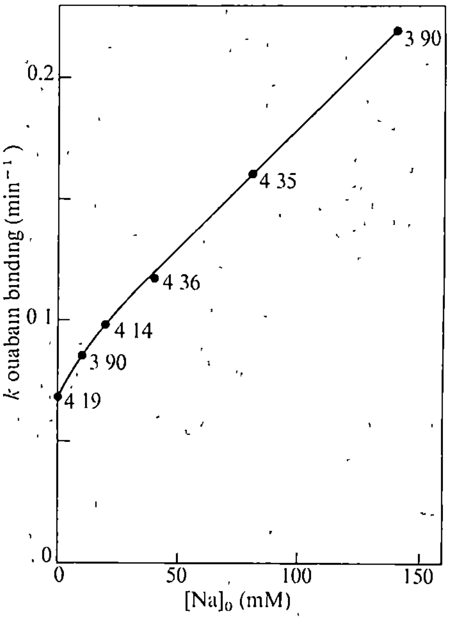

Fig. 2 Promotion of the rate of ouabain binding by external sodium. Cellular cation concentrations were altered using nystatin as described in Fig. 1 so that [Na]$_i$ = 53 mmol per l cells and [K]$_i$ = 43 mmol per l. The rate of ouabain binding was determined by measuring the onset of inhibition of the pump after preincubation for various times in solutions containing 10^{-6} M ouabain, 11 mM KCl, 5 mM glucose, 10 mM Tris-HCl (*p*H 7.5) and NaCl as indicated, with NaCl+choline Cl = 140 mM. Ouabain binding was stopped by addition of ice-cold isotonic choline Cl. After washing by centrifugation, unidirectional influx of K was measured[5] in a medium containing 11 mM KCl, 140 mM choline Cl and Tris-HCl and glucose as before. Thus for each Na concentration a time course of ouabain binding was measured, and the rate constant, *k* (min^{-1}), of binding was determined from the slope of the curve for the time course. The numbers on the figure are ouabain-sensitive K influxes (in mmol per l cells × h) measured in 11 mM [K]$_0$ and Na concentrations indicated but in the absence of ouabain. Fluxes were determined in triplicate and ouabain binding rates in quadruplicate.

the two sites to be filled by Na. Given the "limiting non-zero ouabain-sensitive K influx" described by Cavieres and Ellory in these conditions[2], the minimum requirement of a model for the pump is that two sites can be occupied by Na and one by K simultaneously. Two possibilities are that (1) the external pump form $^{Na}X_K{}^{Na}$ is capable of active K translocation, or (2) additional K or Na sites (for example, the form $^{Na}{}_KX_K{}^{Na}$) are present on the external aspect of the pump.

CAVIERES AND ELLORY REPLY—The finding of an upwards deflection of the $1/v$ against $[Na]_0$ curve would certainly be very interesting. Unfortunately the deviation from a straight line in the data presented[1] is effectively based on only one point ($[Na]_0 = 140$ mM), where the flux is 13.6% lower than it would be for a straight line fit. From the legend to Fig. 1 it is apparent that cell K (~ 8 mM) can be ~ 10% lower in the cells incubated in 140 mM Na medium, thus reducing the K influx by ~ 5% (ref. 6). If the further contributions of experimental error (up to 3.9%) and the scatter (for example, for $[Na]_0 = 10$ mM) are considered, it becomes difficult to defend the departure from the straight line fitted through the remaining data. In fact, from inspection of our earlier experiments carried out at a $[K]_0$ of 1 mM, we could find no evidence for deviation from a linear relationship. A final possibility (although unlikely), is that the difference in internal K between our experiments (K ~ 50 mM) and theirs (K ~ 8 mM) may have a role.

Haze in the stratosphere from the Fuego eruption

SCORER[1] reported seeing an extended haze layer during Concorde flights at heights up to 17 km (56,000 feet) on September 1, 1975 from London to Gander and back. He assumed that this was the result of large scale ascent of normal tropospheric dust. On the premise that this was indicative of the normal interchange mechanisms across the tropopause, he then concluded that the theories which have led to the recent 'ozone depletion scares' are based on 'nonsense' suppositions regarding the nature of the vertical transport in the stratosphere.

A much more likely explanation of the haze layer observed by Scorer is that this was aerosol remaining from the material injected into the lower stratosphere by the violent eruptions in mid-October 1974 of Volcan de Fuego in Guatemala. A number of different investigators reported the appearance of a haze layer (or layers) between ~16 and 20 km during the following months[2]. Further observations during the past year, with lidar[3], twilight measurements[4], dust sonde[5], and searchlight measurements[6] indicate the continued presence of this dust layer over Hawaii, Puerto Rico, and northern midlatitudes. It is probably still present over the Arctic, but it is not known whether any dust reached the Southern Hemisphere. According to the lidar data the layer has diminished slowly since early spring 1975 with a residence time of ~6 months—about half that of large volcanic events. Measurements at several locations show, however, that purple twilight glows are now (after a minimum in April) nearly as strong as those of winter 1974–75. The haze phenomenon described by Scorer has often been studied in colour photographs obtained by time lapse cameras flown on balloons, mostly over New Mexico[7]. In the flights from December 1974 to the most recent in October 1975, strong haziness near the solar azimuth extends to ~20 km. If the Sun is not high up, a rather sharply bottomed haze band appears at a balloon altitude of ~16 km. When the balloon is in the main layer, the distant horizon disappears, and thin layers may be noticed briefly. When the balloon is leaving the layer the distant haze top becomes sharp and edged by deep blue sky. Optical measurements showed very little aerosol in the region of the layer in question during 1972–74, but some thin layers could always be detected in the balloon photographs because of the great path length.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

Zenith attenuation of solar radiation by the Fuego dust was hardly >1%. Therefore the change of Earth temperature was ~0.2 K only[8], and the effect on vertical transport less than that suggested by Scorer.

SCORER REPLIES—A characteristic of the occasion on which I observed the haze was that there were cirrus clouds above the tropopause and the tropopause itself was not apparent to the eye. After a year I would have expected purple twilight to have been much decreased, as the note says it was in April, and the large vertical extent of the haze suggested that it was not very old, otherwise it would have been sheared over into thin layers, of which several would be unlikely to be found together over one geographical location.

On the assumption that such layers come from volcanic eruptions, anyone determined enough can, of course, ascribe them to the one they think to be the most likely cause; but it is important to recognise that the assumption can dominate thinking about these phenomena. That explanation is not "more likely" except after acceptance of the assumption.

I do not see what attenuation of solar radiation or change of Earth temperature have to do with the radiative equilibrium, which I supposed was dominated by a change in the absorption of the outgoing long waves.

Reiter[1] gives a spread of residence times for stratospheric air ranging from 80 to 1,000 d at 20 km, which seems reasonable. Therefore to ascribe finality to any explanation of the haze is possible only if it can be traced accurately back to its origin. What I am suggesting is that there are probably many manifestations of the mass-interchange mechanism not yet properly investigated, and that hurricanes could be involved to an important extent.

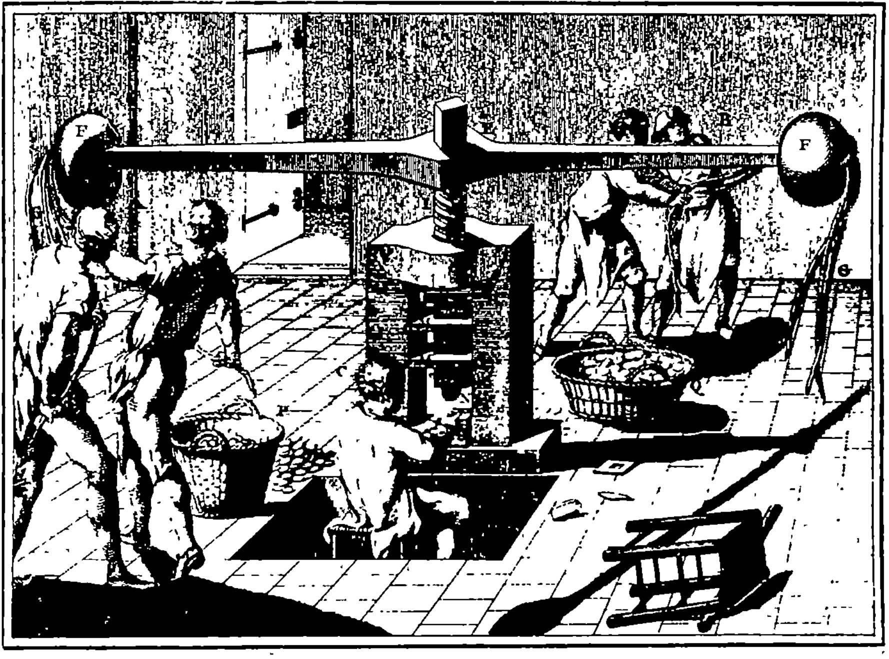
reviews

A double life

J. W. Herivel



Machinery of the Mint, as illustrated in the Encyclopédie *(Paris, 1771). The great screw-press (a fly-press in modern terms) which impressed the round blank.*

THE period covered by this volume witnesses the continuation, and exacerbation, of the controversy between Newton and Flamsteed, and the initiation of that with Leibniz over the question of priority in the calculus. Throughout the period Newton continues in his dual role as Master of the Mint and President of the Royal Society. His activities in the former role are copiously documented, those in the latter much less so. Compared with the previous period, and excluding the letters and papers relating to the Mint, there is perhaps a certain narrowing of Newton's correspondence in this volume. Thus there are now no letters to or from Locke or Halley. But any such restriction is more than compensated by the presence of the whole of the magnificent correspondence with Cotes over the preparation of the second edition of the *Principia*. Although Newton had long ceased to be mathematically or scientifically creative, the correspondence with Cotes proves that his intellectual energies remained undimmed. Apart from certain of the Mint letters, he also continues to write in a style marked by that concision, clarity, and strong sense of word order, first displayed in his 1672 paper on colours.

Almost all the Mint letters and memoranda are here published for the first time. On the whole, they are not the most interesting of Newton's letters, but there are exceptions, such as the memorandum (816a) "Of the assaying of Gold and Silver, and the making of indented Triall-pieces and trying the moneys in the Pix"; a measure of the importance which Newton himself attached to this memorandum is given by the fact that it exists in no fewer than eight drafts among the Mint papers. Among the letters relating to the Flamsteed controversy, a blistering letter (825) to Flamsteed about which Newton probably had second thoughts, and a hitherto unpublished letter (853) to Flamsteed from his "quondam friend and not yet profligate Enemy" Halley are noteworthy. Also another hitherto unpublished letter (978) to Flamsteed from a Committee of the Royal Society requiring the unfortunate Astronomer Royal to send them a copy of his observations for 1712 in accordance with "Her Majesty's Most Gracious Letter of 12 December 1710"—the warrant (reproduced at 814) extracted by Newton from the Government, requiring Flamsteed to surrender up his observations for any given year within six months of its ending.

Surprisingly few letters and memoranda relating to the Newton–Leibniz controversy are found in this volume But as the editors point out in their introduction, this is no index of the time which Newton actually devoted to the controversy, inevitably at the expense of other activities including his correspondence with Cotes over the second edition of the *Principia*. When drawing up his celebrated edition of this correspondence, Edleston did not have access to the Portsmouth Collection. This accounts for the appearance of no less than 12 new letters between Newton and Cotes here published for the first time. Taken together, these represent such a substantial addition to the Newton–Cotes correspondence as almost to call for a new edition, preferably with a fairly detailed exposition of Newton's lunar theory in an appendix For although the introduction and notes to the present volume are very helpful in this respect, they still leave much obscurity occasioned in part by Newton's habit of carrying out long lines of reasoning without the use of symbols.

Among the new letters, number 829 throws interesting light on Newton's original intention to thank Cotes publicly for his vast (unpaid) assistance with the preparation of the second edition of the *Principia*. As suggested by D. T Whiteside, the apparent cooling in Newton's relations with Cotes towards the end of the enterprise may possibly have been due to Cotes's failure to notice the error in Proposition 10 of Book II first drawn to Newton's attention by Johann [I] Bernouilli, (see 951a) in circumstances which the controversy with Leibniz rendered embarrassing to Newton. Of letters and memoranda on other miscellaneous topics the following, all hitherto unpublished, are noteworthy; number 802, in Newton's most pithy

---

The Correspondence of Isaac Newton. Vol. 5: 1709–1713. Edited by Rupert A. Hall and Laura Tilling. Pp. li+439. (Cambridge University: London, October 1975. Published for the Royal Society.) £20.

Mr Herivel is a reader in the Department of the History and Philosophy of Science at Queen's University, Belfast, Northern Ireland.

style, with its triumphant announcement of his purchase of new premises for the Royal Society; number 878, in which Newton announces the death of Colonel Robert Barton to his widow's father leaving the latter "discretion to let her know it by such degrees and in such manner as may least afflict her"; number 918, of interest for Newton's views on gravitational attraction; and number 961a, an important memorandum *De Vi Electrica* concerned with Newton's views on attractive forces. The volume is brought to a fitting close by Bentley's letter (1002) to Newton, announcing the publication of the second edition of the *Principia*.

No review of this volume would be complete without a tribute to the late J. F. Scott, editor of volume 4, whose untimely death, following so closely on that of H. W. Turnbull, was such a loss to this great project. It is to be hoped that the present editors will be able to carry it through to completion. Their editing of the present volume, including the footnotes and an admirable introduction, maintains the high standards set by preceding volumes. and makes it clear that no better choice of editors could be made for the project's final stages □

Universal pictures

The Amazing Universe. By Herbert Friedman. Pp. 200. (National Geographic Society: Washington, DC, 1975.) $4.25.

THE May 1974 issue of *National Geographic* included a feature on "The Incredible Universe"; this book develops the theme further with a new text by Herbert Friedman and a lavish use of colour illustrations. I am slightly disappointed, however, that the most has not been made of the opportunity to provide an account of the most intriguing theories of the new astronomy, and that the book largely rests on its illustrative laurels. Nevertheless, it is remarkably good value and helps to plug the gap between conventional 'popular' astronomy books and the revolutionary developments that have taken place in the past ten years or so.

Friedman has concentrated on discussion of the techniques of the new astronomy, which have opened up new parts of the spectrum and other areas to observation, but he does not complete the guided tour of theoretical work we have been led to expect. On solar neutrinos, for example, after describing the Davis experiment, we are merely told that "if the cleaning-fluid trap produces no neutrinos, the mystery . . . may force solar physicists to re-examine their theories"; the "mystery" of Sco X-1 is described as "a continuing challenge for today's Eddingtons", when in fact the source now seems to be well understood; Weber's gravitational radiation claims are to be "interpreted with extreme caution", when there is now a clear consensus which the author does not report; and the mention of apparent faster-than-light separations in some QSOs is followed by the vague comment that "some ingenious explanations for this have been put forward", when those explanations seem both straightforward and a clear indication of the illusory nature of the measured superlight speeds.

Even the professional astronomer may enjoy the pretty pictorial record, and as far as it goes *The Amazing Universe* is good value both in appearance and scientific content. It would make an ideal gift for a young reader freshly interested in astronomy, with the proviso that the donor should take care to follow this up with more meaty texts if the bait is taken.

Photochemistry

Concepts of Inorganic Photochemistry. Edited by Arthur W. Adamson and Paul D. Fleischauer. Pp. ix+439. (Wiley Interscience: New York and London, August 1975.) £13.30.

THIS volume gives an account of the developments in coordination photochemistry, each chapter being contributed by an authority in the field. Two chapters deal with photophysical processes: the first is a brief survey of the electronic spectroscopy of complexes, the second an account of the kinetics of photophysical processes based on concepts well established in organic photochemistry. Against this background are set chapters on charge-transfer photochemistry, substitutional photochemistry of first-row transition elements, and on the photochemistry of the heavier elements, of carbonyl complexes, of 1,3-diketonate chelates and of simple inorganic ions in solution. In each of these chapters the existing experimental information on selected systems is critically reviewed and an attempt is made to interpret the data in terms of principles governing the reactivity of the excited state. The last two chapters are more speculative. The first deals with photochemistry in the solid state, a challenging field of great importance in which the difficulties of obtaining quantitative information and of interpreting it, are formidable. The brief final chapter on photochromism and chemiluminescence concentrates on general principles. It includes the novel suggestion that the "thermally equilibrated excited state" in photochemical reactions may be identified with a particular modification of the "transition state" postulated in thermal reactions.

These are stimulating reviews which give an excellent account of the present state of a rapidly developing subject. Overlap between chapters has been kept to a minimum; a degree of uniformity in terminology and treatment helps to emphasise the common factors in different areas of the subject. A minor source of irritation, however, is the inconsistency in the use of units—the variety of captions for wavelength and wave number, for example.

The book will be welcomed by investigators in the wide field of inorganic chemistry. With its emphasis on concepts and interpretation it should be of general interest to many inorganic chemists.

M. I. Christie

Coherent calculus of subjective probability

Theory of Probability: A Critical Introductory Treatment, Vol. 2. By Bruno de Finetti Translated by Antonio Machi and Adrian Smith Pp. xviii+ 375. (Wiley: London and New York, 1975.) £10.50.

THIS is the second half of the English translation of Professor de Finetti's Italian *Theory of Probability*, and completes a work which, in the opinion of the foreword, "is destined ultimately to be recognised as one of the great books of the world" In reviewing the first half, besides sketching the background to the controversies which occupy the minds of many statisticians, I noted that it was the second volume which would carry Professor de Finetti's critical discussion of inductive reasoning and statistical inference, and that I awaited it with impatience (*Nature,* **251**, 262, 1974). Now that it has arrived, it is slightly disappointing, although in other respects the author presents an invigorating and wholly delightful account of some fascinating topics in probability theory. In treating these (chapters 7–10) he greatly strengthens his Bayesian position by his deft treatment of paradoxical examples (it would be too much to call these teasers of probability theory *paradoxes*). Studded with illuminating asides and revealing anecdotes, this part of the book is a delight. How many statisticians know that the points of inflexion of the normal distribution are at the one-standard-deviation points? Professor de Finetti knows that the tangents at these points cut the axis at the two-standard-deviation points, and such asides give the book its flavour.

Chapter 11, 'Inductive Reasoning; Statistical Inference', is the kernel of the book. "It is particularly instructive to consider the process by which new scientific theories are formulated. The first step is an intuitive one, arising out of some particular set of observations, but then various modifications are made as a result of more up-to-date results which suggest that this or that alternative theory provides a better explanation". So far so good, but what is to be the currency of explanation? I would say *likelihood,* but for de Finetti: "In essence, it is always a question of analysing the current state of information by means of Bayes's theorem". Later, "In our formulation, the problem of induction is, in fact, no longer a problem: we have, in effect, solved it without mentioning it explicitly. Everything reduces to the notion of conditional probability".

The author presumes on our acquiescence, and we look in vain for arguments which will lead the doubting majority to join the congregation of the Reverend Thomas Bayes: why should scientific hypotheses be treated like statistical events? If they should be, *then* the Bayesian position surely follows. for I believe de Finetti carries that part of his case—that the right calculus for events of uncertain outcome is the coherent calculus of subjective probability: it is, perhaps, his major contribution. Bayes, I think, would have approved; indeed, de Finetti could with profit have included an analyis of Bayes' paper in his book, for the one presages much that is in the other.

In fact, Bayes did not include scientific hypotheses in his scheme: that proposal is neo-Bayesian. But whatever we call it, it is the crucial issue. For me it is neither a reflection of how science does progress nor a paradigm for how it should. If universally applied it would reduce creative scientific activity to the level of accountancy. Coherence has its place, just like the double-entry book-keeping introduced by de Finetti's compatriots—the Lombard bankers of long ago: *c'est magnifique, mais ce n'est pas la guerre.*

But let each reader decide for himself. de Finetti's two volumes are essential reading. **A. W. F. Edwards**

Bowl (diameter 30 cm) found as part of a grave lot. New Mogollon pottery style of the 10th century AD, Mimbres area of south-western New Mexico. The Blood of Sheep: Composition and Function. Edited by M. H. Blunt. Pp. xiii+224. (Springer: Berlin and New York, 1975.) DM 72; $31.

This is not a haematological text: the leukocytes receive scant attention, and the platelets and coagulation do worse. Instead it is a collection of chapters by different authors on body fluids, cells, carbohydrate and lipid metabolism, minerals, hormones, genetic markers, haemoglobins, immunoglobulins and anaemias. Each chapter is a factual review with little discussion, and occasional overlap with its fellows. More discussion would have been welcome and more selective editing could perhaps have provided the space. There seems little need in a work of this kind for a description of the actions of each hormone, irrespective of what is known about its presence in the sheep. The chapters vary between crisp, direct succinctness and a lengthy struggle to be comprehensive, and each provides numerous useful references. Nevertheless, because of its layout and index the book proves difficult to use as a reference work. Such criticism should not detract from its usefulness in bringing together a great deal of very interesting material for those centres where the sheep is a major object of study, and their libraries should acquire it.

The individual worker who confines himself to a single aspect of the sheep may find it of only ephemeral interest, and it is too expensive for that. It will prove even more expensive if he injects either of the two doses of adrenaline quoted incorrectly on page 33 from two quite separate sources. Each is a 1,000 times too large.

Brian Greenwood

Optics and Its Uses. (Modern University Physics Series.) By G. F. Lothian. Pp. 218. (Van Nostrand Reinhold: New York and London, September 1975.) Cloth £7.50; Paper £3.85.

Derived from a lecture course, this book is an undergraduate text which includes mention of modern developments such as lasers, non-linear optics, holography, integrated optics, Fourier transform spectroscopy, fibre optics, spatial filters, and so on, as well as dealing with basic theory. In a text of this length it is impossible to cover this very wide range of topics in depth, and reference to some is almost in note form. Although the consequent large number of section and sub-section headings break the flow in places, the arrangement should be helpful to a student, enabling him to make easy reference to a particular topic. In proceeding to an honours degree it would be necessary, as the preface suggests, for a student to supplement his reading, and most chapters refer to specialised books. The reader is expected to work through examples which are contained in relevant places throughout the book. As the title indicates there is emphasis on optical instruments and equipment; and understanding these is helped by a large number of good drawings, photographs, and tables. The latter illustrate a particularly useful feature of the book in providing an unusual amount of numerical data which would not otherwise be easily available to a student.

W. J. Bates

Books brief

Lord Rutherford on the Golf Course. By F. G. Mann, Trinity College, Cambridge, UK. Pp. 33+6 plates. (Published privately.) £1.50, UK; $4.00, Overseas and US. Copies from the author.

An accumulation of anecdotes, most, but not all, about Rutherford and golf. An absolutely bizarre story about Aston and a rice pudding. Nicely produced, but present-day prices hardly help such ventures even when published privately. □

Applied Geophysics. By W. M. Telford, L. P. Geldart, R. E. Sheriff and D. A. Keys. Pp. xvii+860. (Cambridge University: Cambridge and London, January 1976) £26.

The book is a very good one, written and illustrated with clarity. It sets out what is done in the present day in the application of geophysics to exploration. For each method the theory is given in sufficient detail for understanding that method, with the mathematical development to support it. Implementation of the method is described, with practical examples Further problems are given for the reader to solve, and each method has a good bibliography.

Two large sections of the book have special merit. A long chapter on the seismic method is a unified account of the sophisticated technology to which many have contributed time and money: it is almost a single line of development By contrast the chapters on electrical, electromagnetic and related methods bring together a great diversity of methods and practice under a common theoretical and descriptive treatment. Chapters on other methods are written with the same authority and clarity; the exception is, perhaps, the chapter on well-logging. This gives the impression of being an afterthought; and it suffers by comparison with the rest.

There are a few criticisms. The writers do not distinguish everywhere between interpretation and modelling, the inverse process. Time domain sampling at 4 ms intervals does not correspond with frequency domain sampling at 250-Hz intervals (p375). The noun 'practice' is not spelt with an s.

The book should fill the requirements of university teaching and of company training programmes It is of value to professional geophysicists who can rarely keep up with geophysical literature outside their speciality.

A. A. Fitch

An Introduction to Non-Numerical Computing. By Patrick A. V. Hall. Pp. 193 (MacDonald and Janes/American Elsevier Computer Monographs) £2.95.

This is a very competent collection of methods, algorithms and exercises divided into chapters on "Abstract Information and Algorithm Structures", "Machine Structures", "String Processing", "Files and Tables" and "Sorting". The book forms a reliable textbook of available techniques; it does not break any new ground but current thinking is well expounded. Hall's views on flow-charting are well worth noting. My only criticism is that a book on non-numerical computing should adopt a style different from mathematical texts. It is not that the mathematics is difficult—it has, in fact, been kept simple—but the flavour is still mathematical. References are also made to details of earlier chapters although the author says that the later chapters can be read in any order. The way in which the algorithms are presented also causes some difficulty, being a mixture of precise ALGOL-like instructions and English statements: but one soon adapts. The book is intended to support a second course in computing and leans heavily on ALGOL 60. Perhaps it could more usefully be based on ALGOL 68; it would appeal to a wider audience if it had been based on COBOL. The work is well illustrated and indexed. The exercises at the end of each chapter, although perhaps a little difficult for second course students, will be extremely valuable for teachers.

R. D. Parslow

obituary

Werner Heisenberg died on February 1, 1976. His youth was inspired; he lived through a long war which destroyed cities, lives and the spirit of people; in his old age he tried to rebuild a great tradition which had been virtually wiped out by Hitler.

The beginning of this century was the most remarkable period in the history of science. It was, in fact, so revolutionary that most people, including the majority of intellectuals, have failed to grasp what has happened. The leaders of this revolution were Heisenberg and his great teacher, Niels Bohr. The result was a complete explanation of the world of the atom. This fact is known. But the philosophical implications are all but forgotten. The philosophical principle is called 'Complementarity'.

Complementarity, or its older designation, dualism, is not new. It is as old as man. What are you: a piece of matter or a soul? It is difficult to deny etiher body or spirit. But to believe in both was considered sheer mysticism by a generation of scientists who lived in a world in which truth seemed to be simple.

It was Bohr who introduced a peculiar element into the most straightforward of all experimental sciences, physics. He based his quantum theory not on an explanation but on a contradiction. His ideas caused consternation, but his successes could not be denied.

Heisenberg, barely 24 years old, created order where there seemed to be chaos. Where Bohr navigated a new ocean keeping the shore of classical physics in sight by the use of the correspondence principle, Heisenberg left the old land and sailed beyond the point of no return. He found the New World of quantum mechanics. (It is even more remarkable that in inventing 'matrix mechanics' he did not know anything about matrices—he reinvented them.)

The unity of physics was reestablished by the cooperation of Heisenberg and Bohr. They asked the essential question: are atoms made of waves or particles? The answer: we cannot explain atoms without using both the wave picture and the particle concept. The two can be reconciled by setting limits to the accuracy in applying either description. For instance, the more accurately we know the position of a particle the less accurately can we know its velocity (or momentum). This is Heisenberg's 'Uncertainty Relation'. His first illustration was based on the resolving power of the microscope, a point on which, amusingly, he was ignorant at his PhD examination.

What has this to do with the body–spirit dualism? Heisenberg has shown that two obviously contradictory concepts, waves and particles, are not only necessary in explaining the structure of atoms but also, these two concepts can co-exist within a single rigorous mathematical formalism. If this can be done today for atoms why should it not become possible to do something similar someday in describing life or even a human being? Whether anything of the kind will happen one cannot tell. But Bohr and Heisenberg did something which even in the context of the great intellectual accomplishments of modern science is quite exceptional.

Werner Heisenberg, Photo: Associated Press

One often has the feeling that discoveries are just waiting to be made. Most scientists, even the great ones, merely accelerate science. They don't change it. Bohr and Heisenberg gave a completely new turn to the understanding of the world. Without them this understanding may never have come, at least not in our present culture. (This may sound like an exaggeration but I remember Bohr's statement: "If I can't exaggerate, I can't talk.") Without them the science of the atoms may have developed into a formalism even more remote from the common, unmathematical understanding than it is today. Without them the intricate concept of the interaction between the observer and the object may have been missed. (Heisenberg modestly denied this; he said that he only found what was there.)

Of course, the prime mover was Bohr. He was far ahead of everybody, but he was obscure, almost oracular. It was Heisenberg who brought the wisdom of Bohr (which Bohr managed to hide in his own words) to the level of lucidity where the common-or-garden theoretical physicist and mathematician could understand it, if he tried.

But in performing this translation of philosophy to exact science, Heisenberg did not lose any of the great original concepts. The philosophy (not coming from a philosopher) might have been lost. The science will survive. This is why Heisenberg is one of the few who have truly changed the world. It can never change back.

Heisenberg was made a professor when he was 26, and I became one of his students. We all talked physics, and played ping-pong and chess, and in this close environment a lot of fundamental work was done. Heisenberg received the Nobel prize in 1932 for the historic discovery of quantum mechanics and its implications, but much of his additional work would have sufficed in its own right to earn that distinguished honour. Some milestones are: papers on quantum field theory (QED with Pauli (1929, 1930) and divergence problems (1934)—Heisenberg's positivism can be exaggerated!), work on the solid state (the first understanding of ferromagnetism (1928)) and on symmetries (the distinction between ortho- and para-helium and hydrogen) and the invention of iospin (1932). We knew that the world was open and the key was reason.

Then came Hitler and reason was no more. In the summer of 1939, Heisenberg visited the US. Several of us asked him to stay. His answer to me was: "If your brother had stolen a silver spoon, he is still your brother." It was much more than a silver spoon. Both of us knew it, but neither of us could say so.

During the war Heisenberg worked on atomic energy. He used his position to save the lives of several fellow physicists. In his project he got nowhere. Why was Heisenberg unsuccessful in his wartime job? I am sure that the reason was not any lack of ability. I believed firmly that the obstacle was the silver spoon.

In his last years he wrote the story of his great experiences in science and the story of the tragedy of the deeply troubled times in Germany. In his writings, it becomes clear why Heisenberg failed during the war. He was happy to see that the technical difficulties were enormous and he concentrated on peaceful reactors. He only hoped that the American scientists, including the refugees from Europe, would come to the same conclusion. In 1941 he visited Bohr to give him this message. But Bohr's ears were closed and Heisenberg knew that he must continue to live in a small island surrounded by the Nazi horror; the greater world was too far away; even his best friend had turned his back. Bohr later escaped to the US, but Heisenberg's message was never delivered.

I shall not forget one of Heisenberg's recollections. With a colleague, he is hurrying through burning Berlin, trying to get back to two of his sons when his shoe catches fire. And while he puts out the fire, he discusses with his friend how science will be rebuilt in Germany when the catastrophe has run its course.

Shortly after the defeat of Germany, he hears of Hiroshima. He can hardly believe it. He is convinced that a political movement, or country, must be judged by its methods, not by its professed aims. (Heisenberg never mentions a nightmare which must have occurred to him: what would have happened if atomic bombs had been used against Germany. Hitler, unlike Hirohito, would not have had the fortitude to surrender. Hitler wanted Germany destroyed if the war was lost.)

But at last peace came and the reconstruction started. Heisenberg returned to the land he loved most, Bavaria. He continued to work on the hardest and most exciting problems of physics. The same basic philosophy that had led him to his formulation of quantum mechanics took him to the S-matrix approach to particle physics (1946). He later devoted himself to a bold attempt to understand particle physics through non-linear field theories with an inherent 'length' scale—continuing, in fact, pre-war ideas. This expressed his opposition to the idea that there are never-ending hierarchies of successively more fundamental particles— the 'big fleas–lesser fleas' syndrome. He also initiated the German programme for the production of nuclear energy.

In a long, magnificent and difficult life he never lost his sense of purpose, nor a sense of humour. On the 800th anniversary of the Bavarian state, he appeared on television and said: "The Bavarian unites the discipline of the Austrian with the charm of the Prussian." Most particularly, he retained a sense of balance. To each serious argument, he attached its opposite. He understood, from his own physics that between 'yes' and 'no' there are possible answers, less abrupt and more fruitful.

I am one of the relatively few who had a teacher like Heisenberg. From his life there remain for me two lessons. One is that the cataclysm of yet another world war must be avoided. Next time, though man will surely survive, it will be even more difficult to imagine how the spirit can be resurrected. The other is that the path of peace is not only difficult but also uncertain. No simple proposal, neither power nor appeasement, will suffice.

The title of Heisenberg's memoirs *Der Teil und das Ganze* means literally the part and the whole: the world cannot be divided into science and politics, nor into any other components. It is strange and wonderful that this lesson of unity should have been taught by a physicist who worked on a subject that most consider remote from the common understanding.

Don't sit on the milestone

It is with some sense of relief, even pleasure, that it can be reported that the United States and the Soviet Union have actually managed to conclude an agreement on limiting underground nuclear tests to yields of less than 150 kilotons. Two months ago we were gloomily predicting that the superpowers would not meet their modest deadline of March 31, and we were wrong. In the process of negotiations it looks as if some real headway has been made towards establishing the principle of on-site inspection so important to the Americans, worried about cheating, and so tiresome to the Russians, worried about espionage. It has been agreed that the explosives for peaceful purposes shall not come in quantities of greater than 150 kilotons separately, although several may be fired simultaneously. Inspectors will monitor adherence, presumably by some down-hole device attached to each explosive to measure yield.

The satisfaction is that the threshold treaty, despite everything, is intact and the superpowers have done what they said they would. The vigour of the Soviet Plowshare programme, in which projects as big as the diversion of rivers still feature, has always been a worry to those who saw a treaty and a peaceful programme as incompatible for arms-control purposes. The neat formula by which this worry has been resolved offers some hope for future developments within the same framework.

This week's Geneva conference on test-ban monitoring will no doubt grudgingly acknowledge the Soviet-American agreement, but participants will also go on to say, privately if not in public, that

- Bilateralism is too cosy
- 150 kilotons is too high
- efforts to lower the threshold must go on.

Both superpowers have been vigorous in their high yield weapon-testing in the run-up to the treaty. In the United States advanced development research and testing has been put off for the last year and a half, according to ERDA's congressional supporters, while work was directed towards preparing for the treaty. There is thus a great danger that now that a milestone has been reached, the superpowers will sit on it. What better than that the Swedes, the Japanese, the Canadians and all other countries which have tried for years to make the superpowers see that vertical proliferation is as offensive as horizontal proliferation, should urge a painless formula gradually to reduce this threshold to zero. Such as:

$$\text{Threshold} = 150(1 - (\text{Year} - 1976)/10) \text{ kilotons.}$$

And how about some positive support for their efforts from the United Kingdom which has too much in recent years adopted a don't-rock-the-superpowers'-boat attitude engendered by nuclear subservience to the United States?

Mixture as before

Anyone who thought that, because of the prominence given to the fight for the Labour leadership, the consequences of Harold Wilson's departure might entail a different if not more favourable orientation in the UK government's disposition towards science, can be forgiven for feeling frustrated. Under James Callaghan the government has already twice indicated that, in this respect at least, continuity (meaning no change) is the order of the day.

The first, crucial indication came, not with Denis Healey's Budget, but in a White Paper released the same day entitled *Cash Limits on Public Expenditure* (Cmnd. 6440, HMSO). The limits, which apply to more than three-quarters of central government spending not counting social security benefits, are controls on the actual cash that may be spent in the year 1976–77 by specified blocks within government departments. The system supersedes the traditional budget estimates, which subsequent supplementary estimates used to inflate to compensate for escalated prices and costs during the year; now, if prices rise too high, the White Paper says, government purchases would have to be cut back.

The figures make the position clearer. The cash limit on Department of Education and Science's Science Budget, for example, which finances the activity of the Research Councils, is £226.1 million. The voted figure, announced earlier this year, is £215.949 million, and this remains the total available to the Research Councils. The difference represents an amount which could conceivably be available if times became really hard and the needy Research Councils could present a convincing case, to both the Minister and the Treasury, for the created margin of flexibility to operate in their favour. The Department of Energy's expenditure on nuclear energy, to take another example, has a cash limit of £124.4 million, and the same strictures will apply.

What is less clear is how the cash limits are arrived at. They obviously incorporate a government estimate of the rate of inflation for the year—an estimate that is still (temporarily?) secret. But if the declared aim of 10% by the end of 1976 is not achieved, research backed by the councils may not go ahead. And, given the need to contain public expenditure, if the rate ends up lower than forecast, the cash limits could conceivably be reduced.

The other, less crucial indication of a no-change policy, came with Mr Callaghan's Cabinet reshuffle. A glance tells all: Fred Mulley stays at Education and Science, Tony Benn stays at Energy, Eric Varley stays at Industry, Roy Mason stays at Defence (the only major department which has just a single block—of £5,835 million—covering all its expenditure). Peter Shore moves to the mis-named Environment giant.

It is early days yet, but with junior positions unlikely to make much difference, science policy looks for the moment like staying stagnant at the top. ☐

Keeping our heads about our heads

Controversial questions are currently being raised about psychosurgery. Keith Oatley of the Laboratory of Experimental Psychology at the University of Sussex comments on some of the issues

IN THE last few weeks public notice has been drawn to the use of physical and surgical interventions in the treatment of "mental illness". The release of the film "One Flew Over the Cuckoo's Nest", in which both electro-convulsive treatment and lobotomy were portrayed as techniques of punishment and control, was followed by a television documentary of a woman who had bouts of violent behaviour, and who was operated on by a neurosurgeon to remove part of her hypothalamus. The results were then reported of an Inquiry which upheld allegations made at a "typical" British mental hospital that electroconvulsive treatment was given "casually" and on "a disturbingly large number" of occasions. All this comes at a time when the Royal College of Psychiatrists is planning a controlled study of psychosurgery on 200 patients in the London area.

Under these circumstances it seems appropriate to consider some important issues raised by psychosurgery: the attempt to control entirely mental and behavioural symptoms (with no organic pathology) by physical stimulation or lesioning of the brain. Two fairly extreme positions can be taken up, both with a good measure of enthusiasm, righteous indignation, and often some reluctance to examine the evidence.

One position is that psychosurgery is barbaric, infringes patients' rights, and produces irreversible damage to the brain (how can less brain be better than more?). What justification is there in any case, it is asked, for supposing that people who have difficulties in living are "ill" or need to have some part of their brain stimulated or removed?

At the other extreme some members of the medical profession claim that psychiatric disturbances are illnesses with physical causes, that it has been shown that for some of these, intervention in the brain produces alleviation of symptoms, and even cures, and that doctors are in a position both to recommend, carry out and evaluate such treatment. (This latter point for instance was the conclusion of *The Times* medical correspondent Dr Tony Smith. "Only another doctor can be certain that a line of medical treatment was inadvisable, unethical, or simply wrong".)

Neither position squares well either with our physiological, psychological or sociological understandings of psychologically disturbed, or disturbing behaviour. Three kinds of consideration seem to be most relevant. First, there are the reported results of psychosurgical procedures which have already been undertaken. Secondly, there is evidence from experimental animal work (from some of which the psychosurgical techniques were originally derived), and from experimental analysis of, for example, accidental brain damage in people. Finally, there are some fundamental considerations of how people, including doctors and patients, ought to behave towards one another, backed if necessary with legal sanctions. It is worth considering one illustrative example from each of these.

In a recent issue of the *British Journal of Psychiatry* (**128**, 226–240; 1976), N. Mitchell-Heggs, D. Kelly and A. Richardson of St George's Hospital Medical School report on 66 patients given psychosurgery, and followed up over a mean period of 16 months. The operations were multifocal. Lesion-making electrodes were placed sterotactically in 10 sites of each brain (typically three in each frontal lobe, and two in each cingulum). The thermocoagulative lesions were aimed at various limbic tracts, and each estimated at 6 mm in diameter. Before and after operation patients were assessed on an impressive number of scales and inventories, and in 28 cases by a semi-independent assessor (a retired psychiatrist). The report was that 73% of the patients were improved at 6 weeks and 76% at 16 months. The paper is excellently detailed by the usual standards of such reports. The authors take pains to discuss the prerequisites for the operation (that is, an exhaustive trial of less radical treatments), and give a lot of statistics about their assessments.

Various comments can however be made. There is no control group, for example, and with the best will in the world the assessment is done by people who have a strong interest in reporting success of the procedure. Also, although one gets the impression that many patients did benefit substantially from the treatment (various remarks being made about "returning to work" and so on), the measures of improvement did not include assessment of whether the patients were improved with respect to their own objectives in life, or with respect to whether they were easier to contain in institutional care. Moreover, many of the scales used were heavily biased. Clinical rating scales, for instance, had three categories for "improved", one for "unchanged" and one for "worse". It is known that to approximate to fairness, rating scales should be symmetrical about the null hypothesis of "no change".

Regarding the experimental evidence (mostly from animals), this indicates that brain anatomy is no less variable than the anatomy of human faces, that sterotaxic placement of electrodes is in any case subject to errors (for example, of electrodes bending or being misdirected and thus ending up in places other than those planned). Even disregarding these there is no evidence that parts of the brain are related in a one-to-one fashion or any other simple way to categories of behaviour such as aggression or obsessionality. (The best review of these matters in the context of psychosurgery is by E. Valenstein, *Brain Control* (Wiley; 1973)).

Finally, although careful consideration of the experimental evidence from animal work would dissuade one from attempting psychosurgery, it does already take place, and some doctors believe it benefits some extremely disabled people considerably. If psychosurgery is to take place at all, what we do need is a proper trial, with proper controls, with informed consent of all subjects, and the participation of people (other than medics.) who know how to design and assess such experiments.

The trial should compare a group of patients who have been referred for psychosurgery (on the basis of severe disablement and failure of previous treatments). Half should have the psychosurgery, and the other half a further attempt at the best available non-surgical treatment (perhaps a combination of chemotherapy and behaviour therapy). All participants should be given supportive psychotherapy and rehabilitation help throughout. Assessment before and after treatment should be undertaken by several independent people, of different psychiatric persuasions, and without knowledge of what treatment each patient is given.

There are ethical problems; but these are less questionable than the current practice of doctors carrying out research without informed consent of all subjects in ill controlled studies which continue to leave room for doubt about the efficacy of procedures which then continue to be practised. ☐

Science and the media

David Fishlock, Science Editor of the *Financial Times*, looks at two recent publications* on a controversial relationship

SOME YEARS ago, while writing a science feature for a daily newspaper, I was advised by one scientist to ring up another for help on one specific point. But the professor in question, unknown to me, was not willing to talk on the 'phone and suggested I write. I said—perhaps impatiently—that I wanted to develop and verify the point right away and "can't wait three months for a reply". The professor would not budge but did ring my Editor to complain about my "rudeness".

A year or two later I met the professor at a Press conference called by her university to discuss the results of Government-sponsored work in which she had been closely involved. On that occasion she was helpful on everything connected with the Government-funded part of the work, but could not be drawn at all on the (very considerable) commercial implications of her university research. It turned out that she was also advising a large private company.

The readiness with which this university scientist was willing to place part of her knowledge and experience beyond the reach of the public (including her fellow scientists) is a good illustration of the scope for confusion about the respective roles of scientist and journalist. For those scientists who are interested in what the Press and broadcasting channels do with science —and there can be few research workers in these straitened times so unworldly as to be indifferent to the media's activities—these two short books, of identical title, offer a valuable grounding. One is the report of a joint scientist-journalist study group set up by the British Association (BA); the other, a contribution to OUP's excellent Science and Engineering Policy series.

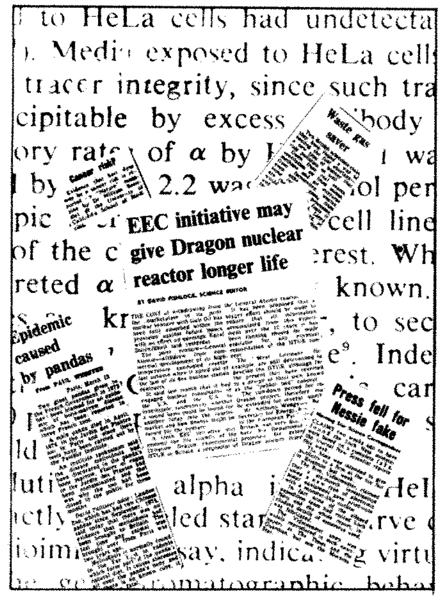
The BA report deals specifically with the quality of the presentation of science subjects to a wider public, improvement in which the BA believes calls for "a much closer relationship between scientists and journalists than exists generally today". It acknowledges that "several factors limit the frankness between scientist and journalist", among them contractual obligations and fears that the information may be over-dramatised. "It is not that he mistrusts the good science correspondent, who can be expected to present issues in a fair and balanced way, but that he fears any airing in the media runs the risk that the story will be taken up, sensationalised and distorted by others".

In 16 pages the BA report sets out very lucidly what the science journalist or broadcaster is trying to do, and why, what handicaps he must work under, and why he is so dependent upon the cooperation of scientists—and good scientists to boot. It has a salutary word of warning about "scientists, mostly with a gift for entertaining the public, who are tempted to exploit the media for personal reasons", and whose ability to dazzle a non-scientific audience may lead them to make "wild and reckless statements". It advises the media to be as wary of such scientists as they are of political adventurers. The corollary of course, is that if the genuine scientist will not help the journalist, he may well be tempted to make greater use of charlatans.

The BA study also touches upon the so-called growing public disenchantment with science, evidence for which it finds is thin. But it suggests that some journalists who believe in it allow their writing to reflect hostility towards science, and thus help to foster hostility between the public and science.

Dr Peter Farago's book covers broadly the same territory at about five times the length. The author is a scientist who edits technical journals and who thus has a toe in both camps. He tends to take a gloomier view of relations between scientists and journalists than the BA working party, which seems to reflect the views of those science correspondents on whom he has relied for first-hand experience of the craft. "The need for scientists to explain was a constant accompaniment to all discussions, together with the hurt accusation that they will not be properly questioned by reporters".

Farago notes that only one newspaper in Britain carries a daily item on science. This is the *Nature-Times* Science Report, modelled on the paper's famous Law Reports, from which I once culled a painfully funny item entitled "Raving and gobbling". There is little danger, however, of anyone doing himself an injury while reading one of its science reports, which are workmanlike but quite uninspired precis of, usually, original scientific papers, tucked away in a "ghetto" at the back of the paper and the bottom of the page.



EEC initiative may give Dragon nuclear reactor longer life
Epidemic caused by pandas
Press fell for Nessie fake

The *Nature-Times* Science Report is a good illustration of some of the major faults and failings of science writing and attitudes towards it today. It is "ghetto journalism" inasmuch as it caters for a select group of readers. Farago found no one on newspapers who found the reports readable—a strong condemnation of any regular newspaper item. They cry out for the touch of a sympathetic editor who knows how to write a good headline, how to inject some flair into the flat prose—all of which can be done, I should assure the purists, without distorting the facts.

But all the skills of the most sympathetic sub-editor could not overcome the handicap of having a guaranteed if inconspicuous place in the paper each day, which insulates it from the need to compete for space and attention. As a consequence it becomes isolated from the substance of all other reporting, no longer part of the fabric of everyday news. This may even redound in attitudes towards other science stories which get less attention because the paper thinks it is already doing its duty towards science by allocating a corner each day.

Neither of these two studies reach any very profound conclusions. They agree that science writing can be very good but often is not, and that it would probably be in everyone's interest if scientists and those who write about their work were to take a more sympathetic view of each other's activities. The seven conclusions set out in the BA report offer sensible advice for improving relations, and include the idea of more closely studying just what the public knows and thinks about science and where its ideas are coming from. □

Science and the Media. (Science and Engineering Policy Series.) By Peter Farago. Pp. 95. (Oxford University : London, April 1976).

WEST GERMANY

WEST GERMANY'S Economics Minister, Dr Hans Friderichs, recently announced that Bonn and Moscow had scrapped joint plans, first mooted some 18 months ago when Chancellor Helmut Schmidt visited Moscow, for the construction of a huge nuclear power station at Kaliningrad (formerly Königsberg) on the Soviet-Polish border.

Under the customary sort of no-cash-involved deal favoured by the USSR, Kraftwerk Union and other West German firms would have built the reactor with West German money (reportedly over £300 million), and given the USSR both the technology and the means of supplying electricity to its industrialised west; the USSR would have paid in the form of deliveries of electricity to West Berlin, which is surrounded by East German territory.

The reason given by Dr Friderichs for the cancellation concerned the USSR's proposals for pricing the electricity, which West Germany's electricity companies regarded as unacceptably high. But the suggestion that the project be abandoned came from the USSR when Dr Friderichs visited Moscow, and it is clear that the high prices sought by the Soviet Union in fact merely ensured the collapse of a deal to which East Germany had taken strong exception because of the inclusion of West Berlin.

The East Germans objected to the idea of greater security for West Berlin implied by the supply of electricity to the city. West Berlin may now have to construct conventional plants, although there is a plan for an underground nuclear reactor, while the Soviet Union, for the moment at least, will not obtain its 1300 MW power station.

- The recent State visit to West Germany by Egypt's President Sadat, widely regarded as further cementing relations between the two countries, included a highly publicised excursion to Germany's large nuclear power plant at Biblis. The possibility that Egypt will be a purchaser of German nuclear technology is not being discounted, particularly as Egypt's Minister for Science, Research and Nuclear Energy, El Guebeily, when he visited Germany at the end of January, was accompanied by the President of the Egyptian Academy for Research and Technology and the Deputy Director of the Egyptian Atomic Energy Authority.

Contracts arranged under the German-Brazilian agreement on nuclear cooperation of June 1975 have meanwhile been signed. They provide for uranium production, processing and enrichment as well as for the construction of nuclear reactors and of a reprocessing plant.

- Closely following publication by the European Commission of its second environmental programme for 1977 to 1981, in which priority is given to reductions in water pollution as well as reductions in waste and noise abatement, a group of West German environment experts has argued in a report presented to the Bonn government that a clean-up of the Rhine river is "primarily a German task" because the greatest share of the pollution is of German origin.

The group also suggests that the cost is "not too high" at about £300 million a year, arguing that the Federal government could bear one-third of this, state and local government could finance another third, while the industries discarging effluent into the river would pay for the remainder. The group recommends an effluent tax for industry to encourage Rhine-based companies to purify their own waste.

The report itself says thermal pollution and heavy metal pollution are not problems, but it does say that Rhine pollution has worsened, with salt and oxygen content often at unacceptable levels. In the week the report was published, however, it was announced from Paris that the environment ministers of Germany, France, Holland, Luxembourg and Switzerland (countries drained by the Rhine and its tributaries) had agreed on steps to reduce the excessive levels of salt.

The proposed scheme, which would start in two years if final agreement is reached, would cost about £6 million, but the ministers were unable to concur on how the running costs (around £450,000 a year) should be shared.

- "To strengthen the reciprocal information and communication process between State and Industry in the sphere of practical promotion of research and technology, and to offer starting points for a constructive critique of State measures". That is the aim of a document on state-aided research, entitled *Förderfibel* ("promotion primer"), published recently by the German Ministry of Research and Technology and drawn up by the Institut für Systemtechnik und Innovations-forschung (ISI). Directed particularly to small and medium size companies and to groups of researchers and inventors, the document has a preface by the Minister, Hans Matthöfer, which sets out a recommended procedure for budding inventors and research workers seeking support. The idea is to reduce the waste of time both by themselves and by officials they will approach. It is the ministry's first-ever detailed guide to government support for research.
- The chemical cycle is turning upwards in West Germany. The country's three major chemical concerns—Bayer, BASF and Hoechst—have all now reported a pick-up in business, matching exactly a similar recovery in Britain. As in Britain, the industry has been through a very depressed period, so much so that the upward trend in domestic trade will need to continue and begin revealing itself in foreign trade too if overall activity, including research, is to attain the sort of levels to which this huge and important sector of German industry has grown accustomed.
- Scientists, as much as anyone else in West Germany's academic community, are concerned about the implications of the tradition known as *Berusverbote*, under which the political reliability of people can be tested before they are admitted into the service of the state. Among the best documented cases in respect of higher education, most involve teachers in the social sciences. Estimates of the overall number of cases of refusal of appointment in the Civil Service go into the hundreds, and the number of screenings into hundreds of thousands.

The academics' concern is understandable: not only does it involve questions of basic human rights; it also affects them directly because they, like members of the regular public administration, are civil servants. The idea behind the practice is to prevent "extremists" taking up public appointments, but the major parties disagree less on the idea itself than on whether debarment should be determined merely by a person's membership of a party hostile to the Constitution rather than the particulars of each individual case. The difference has prevented agreement in the Upper House on the so-called Extremist Bill.

ISLAMIC SCIENCE

Scientists gather in Riyadh

Some two hundred Muslim scientists met at the University of Riyadh in Saudi Arabia last month for the Islamic Solidarity Conference in Science and Technology. Michel Chodkiewicz of La Recherche *reports*

A SCIENTIFIC renaissance in Muslim countries is one thing. An Islamic scientific renaissance is another. The former has begun, more or less successfully, in several countries, the latter remains to be done . . . if it has any meaning at all. For many Westerners, and for some Muslims this last point is far from being proved

This doubt was manifestly not shared either by those scientists present in Riyadh for the "Islamic solidarity conference in science and technology", or by the Saudi authorities who had bestowed munificent patronage on the meeting. Several Saudi ministers participated and King Khaled presided at the opening session. For all of these there was no conflict between Islam and science, either in the principles ("Seek out science, be it as far away as China", the Prophet had said) or in the facts (the brilliance of the abbasid era was witness to that).

But complacent contemplation of past glories must give way now to serious planning for the future, the majority of the presentations and discussion during the conference were very down to earth. From problems of nuclear energy, naval construction and scientific documentation to those of higher education, the subjects tackled seemed to have two priorities that of a better balance within the Islamic world between financial resources and manpower; and that of a very powerful drive for research and development, without which the Muslim world will never reach the "critical mass" above which it will be taken seriously scientifically, economically and politically.

The first of these problems—that of finance and manpower—is particularly evident in Saudi Arabia with its crying lack of manpower. (During our stay the government announced that civil servants were henceforth permitted—even encouraged—to work for private enterprise in their spare time) One of the unofficial aims of the conference was to profit by this gathering of scientists and to organise a reverse braindrain. Amongst the 185 Muslim scientists present, 27 worked in the USA, and it was particularly to them that a call was addressed to come and pursue their work in the Islam world. But researchers or technicians working in the resource-poor manpower-rich Islamic countries (such as Pakistan and Egypt) were also tempted by the salaries offered in the oil states.

In the long run this brain-drain, internal to the Islam world, may well be dangerous. The balance between the "umma" interest (the Islamic community as a whole) and those often divergent interests of constituent states will be difficult to get right Moreover, the scientists working in the non-Islamic world will only return to a satisfactory environment, stimulating professional contacts and so on. The creation of centres of excellence could help resolve this problem: to this end, a first step will be taken quite quickly, thanks to the founding of an Islamic Foundation for Science and Technology, probably at Taif, the Arabian city with the most pleasant climate, which has the added advantage of being near both Jedda, where a huge university is being built, and Mecca, site of another planned university.

On most aspects of the arrangements between Islamic countries, visitors, not representing their countries officially, could only express wishes However, the creation of a permanent Conference Secretariat, entrusted to the direction of the Rector of Riyadh University, will doubtless lead to some concrete action in the fields of, for instance, of documentation and scientific information (unifying the technical vocabulary, publishing scientific periodicals, organising seminars and symposia) and in collation of statistical data needed for planning.

Amongst the Conference's recommendations was the establishment of a consultative body comprising scientists and engineers working in military research and armaments. This initiative gave further substance to the already announced decision that several Arab countries had begun to develop a military-industrial community in Egypt. But to move out in this field from the Arab to the Islamic world will not be without its problems. It is worth noting that in his shrewd and much applauded speech at the final assembly Professor Fazlollah Reza, who was at the conference as a physicist but who is also Iranian ambassador to Canada, made remarks on all the resolutions adopted . . . with the exception of that concerning military consultation, which he passed over in silence.

● **Salah Galal writes:** A total of nine "Scientific Sessions" discussed specific issues. These included natural resources; industrial planning and growth; light and heavy industries and, specifically, chemical industries and manufacturing processes; university education, including its responsibilities towards industry, and technical education and training; research in universities and research centres; and translation and documentation.

It was three special "Projects Committees" which proposed the establishment of the Islamic Foundation for Science and Technology and the establishment of an Islamic Institution for the development of manpower, and produced the recommendations concerning armaments and military research.

RECYCLING

Paper chase

A recent publication from Friends of the Earth, *Ecological Paper Buying,* featuring a variety of recycled paper, urges the extensive substitution of waste paper for pulp as the raw material for paper making, in order to reduce Britain's huge annual pulp import bill. More waste paper, it says, could be used in newspapers, writing and printing papers and tissues, which currently take up 45% of the market.

The FOE spotlight a vicious circle, in which there is little demand for recycled paper because it is not widely available or insufficiently publicised, but not more widely available because there is little demand In fact the matter is more complicated than that As the Waste Management Advisory Council in the UK said in its first report last January, there would have to be an increase of 50% in the usage of waste paper by the early 1980s (compared to 1973–74) to save £100 million a year on imports given existing technology. The value of those imports was £270 million in 1974.

That means an extra 1.1 million tons of waste paper a year, which has to be collected and stored. The problems this presents, coupled with the problems of cyclical demand, seem to make a buffer stock necessary. One estimate of the finance involved in an excess stocks scheme is £10 million—a sum that is apparently not around at the moment ●

correspondence

Genetic engineering

Sir,—In recent months, molecular biologists have discussed the dangers which can arise from careless or ill-advised experiments in genetic engineering, and have attempted, at various meetings, to lay down guidelines as safeguards against these dangers. Since experiments in this field will, for some years to come, be possible only at specialised centres associated with drawing up these guidelines, their voluntary observation provides a degree of protection against dangerous experiments. The reports of such conferences, however, suggest an air of complacency, doubtless unintentional, giving the layman, or the scientist in other disciplines, an impression that all is under control This is dangerous.

Experience shows that it would be utopian to expect that such safeguards will continue to be accepted by all workers in the field. If it appears possible to use genetic engineering to cause damage or disruption for military purposes (several such possibilities can be envisaged), there will be organisations and states willing to sponsor and scientists willing to undertake such research, motivated by intellectual curiosity, or mistaken patriotism, or even a desire for gain and power. Under the circumstances of secrecy which would almost certainly be imposed, voluntary controls would be ineffective

Fortunately secrecy in research is rarely absolute and is difficult to maintain in the face of informed vigilance If the dangers of biological warfare appear to have receded in recent years, it is largely because of the vigilance of organisations like SIPRI, and the discussions stimulated by their reports. When everyone can recognise a danger and can work on counter measures, the danger becomes less acute.

It would thus appear to be an opportune time for molecular biologists to set up their own vigilance machinery, not as a police activity which would be repugnant to most scientists, but as information groups, which collect information on all known ongoing research, and can discuss and publicise the implications and the dangers of such work. Periodical publication of such reports in journals of general scientific interest would create an awareness and interest in these problems, and the publicity might discourage many persons who might otherwise be tempted into clandestine research.

In the present situation, the scientists' only safeguard against misuse of knowledge is the development of informed public opinion. Creation of such opinion should therefore be accepted as a responsibility of those who are exploring newer fields of research

Yours faithfully,

A. N. D. Nanavati

Superstar technologies

Sir—I am very pleased that you considered our report on "Superstar Technologies" worthy of serious attention. Such constructive criticism as yours is important for any subsequent discussion of the report and its recommendations, and also helps improve our work.

The main point at issue between us is this does technology, like science, need peer-review and mutual criticism? We think so; you doubt it. What is our alternative? Apparently not very much, since you are suspicious of any serious restraint (even if only moral) on a technologist's freedom of action, lest he emigrate or his enthusiasm be snuffed out.

The working party was well aware of this point; you will find a reference (No. 27) to the paper by Freeman Dyson where it is argued eloquently. But they and the Council felt that the scope and power of modern technologies are so enormous, particularly in their political, economic and social factors, that self-monitoring by enthusiastic experts is simply not good enough. Hence our introducing the idea of "Superstar Technologies" and hence our advocacy of a Technology Implications Commission with its carefully delineated functions.

Yours faithfully,

Michael Swann

Isolative sound-change

Sir,—It may be suggested that the most important unsolved problem of Historical Linguistics is: why do isolative sound-changes take place? The nature of isolative sound-change is best explained by an example Anglo-Saxon *bāt* changed into Middle English *bǭt* (to rhyme with *fort*), which changed into Modern English *boat;* Anglo-Saxon *hām* changed into Middle English *hǭm*, which changed into Modern English *home* It is possible to add very many examples with Anglo-Saxon *ā* to these two, and, on the basis of these examples, we formulate the sound-changes "Anglo-Saxon *ā* changes to Middle English *ǭ*, which changes to Modern English [ou]" (where [ou] is the vowel-sound in *boat* and *home*, spelt in different ways). This change is not affected by surrounding consonants —some changes are—that is why it is called "isolative".

The reason for sound-changes of this nature is entirely unknown. In fact, rather few suggestions as to a reason have been made; there was, perhaps, more interest in the subject in the nineteenth century than there is to-day. It may be that the problem, if it ever is solved, will be solved from disciplines other than Historical Linguistics—Psychology comes to mind. It seems that self-analysis is unlikely to help. I have an example of an isolative sound-change in my own speech: I pronounce the word *fire* identically with *far* (and so do some other people), whereas many people pronounce it almost to rhyme with *buyer*. And so for all the rhyme-words (*tyre*, *mire*, etc.). This change—[aiə] to [a·] in phonetic terms—has certainly taken place in my speech during my lifetime. But I am not able to say why

Yours faithfully,

Alan S. C. Ross

A hundred years ago

The Rhind Lectures on Archaeology, in connection with the Society of Antiquaries of Scotland, will be given by Dr Arthur Mitchell, commencing on Tuesday last, and continued on the following Fridays and Tuesdays. There will be six in all, and the subject is, "Do we possess the means of determining scientifically the condition of Primaeval Man and his Age on the Earth?"

from *Nature*, **13**, 495; April 20, 1876

news and views

Apollo asteroid Helin

from David W. Hughes

CONSIDERABLE excitement was caused by the discovery in January of asteroid 1976 AA because it has subsequently been found to be the first asteroid whose mean distance from the Sun is less than that of the Earth Eleanor Helin (California Institute of Technology) discovered the object on photographic plates taken with the 18 inch Schmidt telescope of the Palomar Observatory on January 7. It was then a faint 14th magnitude object in the constellation of Gemini. Using 46 observations taken between January 7 and February 3 Brian Marsden (Smithsonian Astrophysical Observatory) calculated the orbit of the asteroid and this is shown in Fig. 1.

On page 691 of this issue of *Nature*, Morrison, Gradie and Rieke of the Lunar and Planetary Laboratory of the University of Arizona report that the asteroid has a mean diameter of 900 ± 200 m and a visual geometric albedo of 0.20 ± 0.07 So Helin becomes the smallest asteroid ever to have its diameter measured accurately. (The asteroid will not be spherical but will have an irregular shape rather like that of Phobos, a satellite of Mars.)

A radiometric technique was used to obtain the diameter and albedo. The principle of the technique is simple. A fraction A (known as the albedo) of the total sunlight striking the body is reflected whereas the rest is absorbed The reflected radiation appears as the visual brightness, whereas the energy absorbed by the body (assuming the body is in thermal equilibrium and non-volatile) is re-emitted as thermal infrared radiation. The ratio between the reflected and re-emitted radiation gives the albedo. Combining this albedo with either the visual or the infrared brightness of the object gives the radius. Unfortunately there a few snags. All the infrared radiation cannot be measured from ground-based observatories as the 8–14 μm and 17–28 μm windows of the Earth's atmosphere must be used Second, the infrared emissivity of the soils and rocks on the small airless asteroid must be assumed as must also the dependence of the albedo on the solar zenith angle and on the wavelength of the incident energy. The rotation of the asteroid causes the unilluminated hemisphere to radiate some part of the absorbed solar radiation at the expense of the radiation from the illuminated hemisphere. The mean temperature of the observed disk is thus decreased by an amount dependent on the rotation period and the thermal inertia of the surface, leading to an over estimation of the radius. Morrison (*Icarus*, **19**, 1; 1973) finds that at wavelengths greater than about 10 μm the flux is sensitive to rotation and that all the above factors lead to a 10% uncertainty in the radius and a 20% uncertainty in the albedo

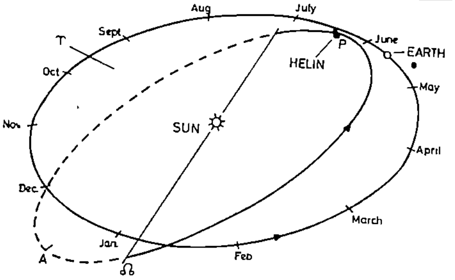

Fig. 1 The orbit of Helin (*IAC Circular*, No. 2915, February 24, 1976). Helin is shown at perihelion (P) and the position of the Earth at this time is also indicated. Helin will reach the aphelion of its orbit (A) on November 9 this year. (γ is the first point of Aries.)

Spectrophotometric studies indicate that asteroid Helin has a surface which resembles that of stoney, silicaceous meteorites and not a carbonaceous chondrite as previously reported (*Sky and Telescope*, **50**, 158; 1976). Silicaceous surfaces seem to be common among Apollo and Amor asteroids.

Helin is the 20th Apollo asteroid so far discovered and joins her more distinguished cousins Icarus, Geographos and Toro in this group of asteroids characterised by having perihelia inside the Earth's orbit.

Shoemaker (CalTech) points out that asteroid Helin is also one of the easiest places to get to in our Solar System apart from the Moon. It makes a most attractive target for an unmanned space mission. Asteroids—half way in mass between meteorites and planets—probably are typical of the building blocks which coalesced to form the planets. Not suffering from convective differentiation and geophysical and atmospheric effects as the planets did, they are most probably in the form of the original condensate from the pre-Solar System nebula and as such furnish an outstanding clue to the origin of the Solar System ☐

Plasmid exclusion and incompatibility

from J. R Saunders

MANY bacteria carry self-transmissible plasmids that characteristically inhibit infection with the same or related plasmids. This phenomenon of superinfection immunity is the result of the presence of two genetically and physiologically distinct barriers, surface (entry) exclusion and incompatibility

Surface exclusion is probably a device to prevent unnecessary mating within a population of homologous male cells Exponential cultures of bacteria carrying a transmissible plasmid are therefore poor recipients in matings with donor cells carrying a homologous sex factor. Exclusion is believed to involve recognition by the recipient of a specific (homologous) sex pilus on the donor and result in blockage of the transfer of DNA. It is mediated, at least in part, by the *traS* gene which forms part of the transfer operon of the F factor (Helmuth and Achtman, *Nature*, **257**, 652; 1975; Willetts, *J. Bact.*, **118**, 778; 1974). But the *traS* product is required only in the recipient and not the donor for surface exclusion to occur The observation that disruption of the mucopeptide layer of donor cells, abolishes the surface exclusion specified by the R plasmid R1*drd*19, whereas similar disruption in recipients has no effect, (Beard and Bishop, *J Bact*, **123**, 916, 1975), is therefore surprising Beard and Bishop suggest that surface exclusion is a barrier to exit of DNA from donor cells rather than, as has previously been assumed, to entry of DNA into a recipient It is presumed that a component (termed ML factor) associated with and dependent on integrity of the mucopeptide in the donor interacts with the *traS* product from the recipient. This leads to prevention of either establishment of stable mating pairs or mobilisation of DNA for transfer Transport of the *traS* product to the donor must presumably occur extracellularly by diffusion or by way of the conjugation bridge established during mating. Detailed molecular studies of the cell envelope of male cells should now help to elucidate the precise mechanism of exclusion.

Assuming that a superinfecting plasmid successfully enters a recipient it may then be incompatible with the resident. Plasmids which are incompatible do not necessarily exclude each other. Incompatible plasmids fail to coexist stably in the same cell and one or other is unable to replicate normally, being eventually diluted from the population. Incompatibility also operates in the case of the F factor whether or not the resident plasmid is inserted into the chromosome (Hfr).

Plasmids have been commonly classified on the basis that their incompatibility indicates a close degree of relatedness Over twenty (in)compatibility groups have been defined (see for example, Chabbert *et al.*, *J Bact*, **112**, 666; 1972; Datta and Hedges, *Nature*, **234**, 222; 1971; Grindley *et al.*, *Molec gen Genet*, **119**, 287; 1972) Members of a group are incompatible with each other but almost always compatible with members of other groups. Furthermore, the phylogenetic relationships established by compatibility grouping have been confirmed by studies of base sequence homology on plasmid DNA (see for example, Falkow *et al.*, *J. gen Microbiol*, **85**, 65; 1974; Grindley *et al.*, *J Bact.*, **115**, 387, 1973).

The mechanism of incompatibility is obscure and complex It may be associated with the process whereby the number of plasmid copies per host chromosome is regulated Some plasmids, for example the F factor, are present as about one copy per chromosome in *E coli* whereas others are present as multiple copies Jacob *et al.* (*Cold Spring Harb Symp. quant Biol.*, **28**, 329; 1963) proposed in the replicon hypothesis that bacterial chromosomes and plasmids both require specific maintenance sites on the cell membrane for replication and/or segregation Incompatibility and regulation of plasmid copy number could therefore be explained by competition for a limited number of plasmid-specific sites This explanation is less satisfactory for multicopy plasmids, which also exhibit incompatibility (Smith *et al.*, *Molec. gen. Genet*, **129**, 229; 1974), unless either the number of specific sites is high or one master copy of the plasmid responsible for governing replication and segregation binds at a single site Furthermore, does F incompatibility in Hfr strains mean that the Hfr chromosome occupies the F site or the chromosomal site, or both? To explain such anomalies it has been proposed that plasmid-specific repressors exist which regulate plasmid copy number. Some support for this comes from studying mutant plasmids which are present as more copies per chromosome than normal (copy mutants). Uhlin and Nordstrom (*J. Bact.*, **124**, 641; 1975) found that copy mutants of the R plasmid R1 fall into two classes. One showed decreased incompatibility with a test plasmid and is assumed to produce a defective repressor of plasmid replication. The other exhibited increased incompatibility due presumably to a defective operator, resulting in increased levels of free repressor. Other mutant plasmids have been isolated which show decreased incompatibility (Inc$^-$) and allow autonomous replication of superinfecting plasmids (see for example De Vries and Maas, *J. Bact.*, **115**, 213; 1973; Wyman and Novick, *Molec. gen. Genet.*, **135**, 149; 1974). These mutants are however chromosomally inserted. Mutations in chromosomal genes can also affect incompatibility (see for example, Bezanson and Iyer, *J. Bact.*, **123**, 137; 1974).

Hiraga (*Proc. natn. Acad. Sci U.S.A.*, **73**, 198; 1967) now reports the isolation of novel F′ factors that can replicate autonomously in Hfr strains of *E. coli.* These plasmids carry a region of the *E. coli* genome including the *dnaA–bglA* region and a specific site designated *poh*$^+$ (permissive on Hfr). Since such F′ factors effectively bypass the normal *inc*-mediated blocking of plasmic replication, Hiraga has proposed that the *poh*$^+$ site represents the origin of replication (*oriC*) of the chromosome of *E. coli. poh*$^+$ presumably functions by allowing these F′ factors to use *oriC*, instead of the F origin of replication (*oriF*) which is blocked by the *inc* product(s) (repressors?) in Hfr strains. It will be of interest therefore to see whether two autonomous F′ factors both carrying *oricC* are compatible. This may determine whether F incompatibility is qualitatively different when the resident F particle is autonomous as opposed to integrated into the host chromosome (Hfr). Complementation studies of mutants of F defective in vegetative replication have been hampered in the past by incompatibility. Therefore the means of circumventing incompatibility afforded by Hiraga's F′ factors may aid in the elucidation of the genetic control of plasmid replication.

Masters (*Molec gen Genet.*, **143**, 105; 1976) also reports the construction of F′ factors carrying the chromosomal region between *bgl* and *mtl* including the origin of replication. It may be significant that this region includes *dnaA*, one of the genes essential for the initiation of chromosome replication. Strains made diploid for the origin of replication by such F′ factors grow more slowly than normal and have a reduced DNA/mass ratio This is to be expected if the ratio of chromosome origins/cell mass is disturbed since this is thought to be involved in controlling initiation of DNA replication (Donachie, *Nature*, **219**, 1077; 1968). Such strains could be used to determine whether control of initiation of chromosome replication is positive or negative It should also now be possible to map the precise location of the origin on the genome of *E. coli.* F′ factors carrying the origin should therefore prove valuable in understanding the mechanisms of both plasmid incompatibility and the control of DNA replication. ☐

Ribosomes and secretory proteins

from A. Amar-Costesec

EUKARYOTIC cells contain two distinct populations of cytoplasmic ribosomes: some are free in the cytosol, others are bound to membranes, which thus appear "rough". Cells secreting proteins very actively have a large proportion of their cytoplasmic ribosomes bound to the membranes of the endoplasmic reticulum (ER). In hepatocytes, which synthesise and export serum albumin and other plasma proteins, 60% of the RNA is present in membrane-bound ribosomes and only 20% in free ribosomes The attached form of ribosomes is predominant in pancreatic acinar cells and in plasmocytes, secreting digestive enzymes and immunoglobulins, respectively In the mid 1950s, Palade suggested that membrane-bound ribosomes are the site of synthesis of proteins which are to be secreted.

When tissues are homogenised, the ER membranes rupture under the action of shearing forces, but then reform as vesicles. The portions of the ER studded with ribosomes are transformed into rough vesicles studded with ribosomes on their external face These rough vesicles retain the ability of ER to incorporate amino acids into proteins. Using biochemical and morphological methods, it was demonstrated that ribosomes bind to membranes through the larger of the two ribosomal subunits, the smaller being attached only to the larger (Sabatini *et al.*, *J. molec. Biol*, **19**, 503; 1966) and that the nascent polypeptide chain is vectorially discharged into the intraluminal compartment of the ER (Redman *et al*, *J. biol Chem.*, **241**, 1150; 1966), probably as an extended chain moving through a tunnel in the large ribosomal subunit. The phospholipid membrane forms a barrier between the cytosol and the intraluminal space.

Blobel and Dobberstein (*J Cell Biol.*, **67**, 835, 1975) propose that ER possesses binding sites in the form of receptor proteins in the membrane. Specific sites on the receptor proteins interact with corresponding sites on the large ribosomal subunit. The receptor proteins form a second tunnel which extends through the thickness of the membrane and is linked to the tunnel of the large subunit. The vectorial discharge of the nascent polypeptide would occur through the two tunnels, resulting in segregation of the protein within the intraluminal space. The main problem, however, is the mechanism by which the cell decides which protein must be segregated, or alternatively how an RNA entering the cytoplasm is able to choose between free or membrane-bound ribosomes.

In 1971 Blobel and Sabatini formulated the 'signal hypothesis' which proposes that mRNAs for secretory proteins possess, after the initiation codon common to all mRNAs, a series of signal codons. When the mRNA is translated by a ribosome, the polypeptide chain then contains at the amino-terminal end a sequence of amino acid residues called the signal sequence The length of this sequence is estimated at 20–25 amino acids, corresponding to 1,000 to 2,000 daltons. When the nascent polypeptide chain emerges from the large ribosomal subunit, it is recognised by the receptor proteins of the ER membranes, which then form the transient tunnel through the membrane. In the intraluminal compartment, the signal sequence is removed by an endopeptidase. Folding of the peptide chain possibly occurs after this post-translational cleavage. The newly synthesised protein is then ready to follow the pathway of exportable proteins through various cell components (such as Golgi, condensing vacuoles and secretory vesicles).

One implication of the signal hypothesis is that exportable proteins are synthesised as polypeptides larger than necessary, as a result of the presence of the signal sequence. Different authors working with heterologous cell-free systems have observed that the product of *in vitro* translation of mRNA for immunoglobulin light chain is larger by about 20 amino acids than the authentic light chain. Similarly, it has been shown that mRNAs from calf parathyroid glands are translated by a wheat germ extract into preparathyroid hormone which migrates more slowly in sodium dodecyl sulphate–polyacrylamide gel than parathyroid or proparathyroid hormones. Here also, the translation product is larger than the normal protein. Another implication of the signal hypothesis is that significant homology, if not complete identity, may be expected in the signal sequence of the polypeptide chains of several exportable proteins. Devillers-Thiery *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 5016; 1975) extracted mRNAs from dog pancreas rough microsomes, and translated them *in vitro* in an artificial system. The polypeptides formed were separated by polyacrylamide gel electrophoresis into five "regions". Substantial homology was found in the sequence of 16 amino acid residues at the amino-terminal end. This sequence, which contained predominantly hydrophobic amino acids, could represent the metabolically short-lived signal sequence of dog pancreas secretory proteins. Another compelling argument is given by the work of Schechter (*Proc. natn Acad. Sci. U.S.A.*, **70**, 2256; 1973) and of Swan *et al.* (*Proc. natn. Acad. Sci. U.S.A*, **69**, 1967; 1972) who have shown that in mouse myeloma, mRNA coding for the light chain of immunoglobulin is larger than that required to code for a native light chain. It is tempting to believe that the additional nucleotide mass could, at least in part, represent the signal codons.

One advantage of the signal hypothesis is that it resolves the old problem of two functionally distinct populations of ribosomes. All ribosomes are equivalent and whether they become attached to ER membranes or remain free in the cytoplasm depends on the mRNA they are translating. The mechanism proposed for secretory proteins may be applicable to other "segregated" proteins, such as the hydrolases of lysosomes, the oxidases of peroxisomes, and some mitochondrial and chloroplast enzymes. Thus, the signal hypothesis could throw light on the mechanism of biogenesis of complex organelles which contain segregated enzymes. □

Amorphous p–n junctions: curiosity or breakthrough?

from Andrew Holmes-Siedle

THE annoying feature about semiconductor electronics is that we are so frequently forced to use single-crystal forms when it would be ideal if we could instead rapidly deposit thin films of semiconductor on an inert, cheap substrate such as silica glass and perform the usual topological processing on these films (for the many advantages of this method, see, for example, Holmes–Siedle, *Rep. Prog. Phys.*, **37**, 699–816; 1974). Unfortunately, without epitaxial growth conditions, deposited films are always either polycrystalline or amorphous. The grain boundaries in the former state make it impossible to fabricate many kinds of device while the main bar to the wide use of amorphous semiconductor films has been our inability to form p–n junctions in them by doping.

Doping in semiconductors is the introduction, often in complex patterns, of impurity-containing regions, in order to modify resistivity and conduction type and form rectifying structures. In the crystalline silicon lattice; for example, a phosphorus atom, having a valence bond to spare, contributes electrons to the conduction band. Until recently, it seemed that this effect was always negated in the amorphous network by the large number of free bonds which could accommodate the space valence bonds of a dopant. But Walter Spear and co-workers at the University of Dundee, working with silicon films deposited from a glow discharge in silane gas, found that these films would respond to the presence of dopants, although they were still non-crystalline by all the usual criteria. Now they report the first preparation of a p–n homojunction structure in a completely amorphous material (Spear *et al*, *Appl. Phys. Lett*, **28**, 105–107, 1976). This was achieved by beginning the deposition of the silicon film in a stream of silane gas containing a little phosphine and then changing the phosphine to borane, or *vice versa*. The devices which were formed had quite good rectifying characteristics, with 'on-off' current ratios which appear to be about a hundred. The 'on' resistances of fairly large-area devices were still quite large by commercial standards (I would estimate them to be of the order of 10^4 ohms for a square millimetre of junction area) but this might be reduced with further work.

The key to the success of Spear's group probably lies in the careful studies which they previously undertook on the physics of amorphous silicon which included the development of a field-effect measurement of the density of states in the mobility gap against potential energy, thereby making it possible to monitor the variations of this fundamental property while the preparation conditions were varied at the fancy of the investigator. Other aspects of the energy-level spectroscopy of these systems also produced useful guidance as to how nearly the mobility gap and Fermi level corresponded to those in single-crystal material of the same doping. 10^{17} phosphorus atoms give a conductivity of 10 $\text{ohm}^{-1}\text{cm}^{-1}$ in crystalline silicon but only 10^{-4} $\text{ohm}^{-1}\text{cm}^{-1}$ in these films and boron seems to operate at a similar level of inefficiency in doping, implying that the characteristic ability of the amorphous network to negate the doping

Standardisation in human cytogenetics

At the Fourth International Conference on Standardisation in Human Genetics, held in Paris in 1971, a Standing Committee was appointed to examine problems relating to standardisation in human cytogenetics and to make recommendations thereon between international standardisation conferences.

During the past four years the Standing Committee has been responsible for publication of the Report of the Paris Conference and a supplement to that report. In addition, the Standing Committee sponsored a workshop on human cytogenetic registries, held in Edinburgh in April 1975 (*Nature*, **256**, 456; 1975) and on the recommendation of this workshop, appointed an international advisory committee on cytogenetic registries.

The terms of reference of the Standing Committee call for elections to a new committee no later than the International Congress of Human Genetics in October, 1976 and the possibility of holding the next standardisation conference at that time. For these reasons the committee has recently circulated recommendations to the participants of the Paris Conference, which have been approved as follows: (1) That a standardisation conference on the lines of the Paris and Chicago Conferences could not be justified in 1976 and, therefore, that no such conference should be held in conjunction with the Fifth International Congress of Human Genetics in Mexico City in October, 1976, (2) That a Standing Committee charged with the task of monitoring developments relating to standardisation and nomenclature in human cytogenetics should be maintained; (3) That an open meeting of all interested human cytogeneticists should be held at the Fifth International Congress of Human Genetics in Mexico City in October, 1976. At this meeting a report of the Standing Committee would be received and a new Standing Committee elected. The existing Standing Committee will be acting as a nominating committee and will be preparing a slate of nominations for consideration by the meeting in Mexico City. These nominations will take into account regional and sectional interests to ensure, so far as possible, a fully representative Standing Committee.

Suggestions for nominations should be sent to the Standing Committee. The time and place of the Mexico City meeting will be announced later and circulated to those requesting this information. Nominations and requests for further information should be addressed to: Dr John L. Hamerton, Department of Genetics, Health Sciences Children's Centre, 685 Bannatyne Avenue, Winnipeg, Manitoba, R3E OW1 Canada.

effect is still prevalent, since roughly 999 out of 1,000 dopant atoms still seem to be suppressed. It remains to be seen whether this apparent inefficiency in doping can be improved on. The important discovery, however, is the fact that even a few dopant atoms are not suppressed. Junction action is thereby produced and a new device technology may even be in the making. The extent to which this technology could compete with single-crystal semiconductor technology depends less on the inefficiency of doping mentioned above, which can be countered, than on the achievement of low minority-carrier recombination-generation rates in the junction regions. High rates lead to high reverse currents in rectifiers and loss of efficiency in photovoltaic applications. It will be a much more challenging task to make these recombination rates suitably low but success in doing so could have a greater impact than the much-researched 'amorphous threshold switch' technology, which now seems to have lost any commercial momentum it ever had. An amorphous p–n junction technology would have much in common with the increasingly popular silicon-on-sapphire technology except that the serious restrictions in area imposed by the dimensions of sapphire crystals would have been removed and the way thus opened for integrated circuits as large as the page on which this column is written. ☐

Superfluid within superfluid

from P. V. E. McClintock

At last, somebody has gone out on a limb and named an encouraging number for the temperature of the anticipated superfluid transition among the ^{3}He atoms of a liquid ^{3}He–^{4}He solution. According to Patton and Zaringhalam of the Massachusetts Institute of Technology, writing in a recent issue of *Physics Letters* (**55A**, 95; 1975), the transition is likely to take place under conditions which can be achieved experimentally.

They are brave men. The first estimates of the superfluid transition temperature T_c of pure liquid ^{3}He were wrong (too high) by a factor of more than fifty. Experimenters eagerly sought the phenomenon, but failed to find it at the predicted temperature: the theorists then increased the sophistry of their calculations and revised their estimates of T_c downwards, a cycle which was repeated several times. This procedure was so utterly demoralising for those doing the experiments (being the classical brainwashing technique of repeatedly raising the victim's hopes and then dashing them again) that, when the superfluid transition finally did manifest itself in Osheroff's cryostat at Cornell, it took several weeks for him and his co-workers to realise the significance of what they had discovered. Hence the notable reluctance, so far, of most theorists to predict a T_c for ^{3}He–^{4}He solutions.

A solution of a few percent ^{3}He in ^{4}He is stable down to the lowest temperatures and is, even without the expected transition, of considerable intrinsic interest. The ^{3}He atoms exist and move in a background aether—the liquid ^{4}He—which is itself a superfluid whose transition temperature lies at the relatively high value of 2 K. At low temperatures, where the ^{4}He entropy is essentially zero, the ^{3}He atoms dominate the behaviour of the liquid. In fact, if one completely ignores the presence of the ^{4}He (except insofar as it results in each ^{3}He atom having an effective mass which is larger than the bare atomic mass), and simply treats the ^{3}He atoms as though they were an ideal gas, one gets the right answers for most of the liquid's properties.

Now, it is known that an attractive interaction occurs between the ^{3}He atoms of a solution and, at a sufficiently low temperature, this is expected to give rise to the formation of Cooper pairs, and hence to superfluidity. It is not yet clear whether the relative angular momentum of the atoms in a pair will be zero, as for the Cooper pairs of electrons in a superconductor, or unity as is apparently the case in superfluid pure ^{3}He. The situation would certainly be very peculiar in either case, however, since the superfluid ^{3}He which was formed would exist in another, completely separate but interpenetrating superfluid, the ^{4}He, which is fundamentally different in nature in that it does not acquire its superfluidity through the formation of Cooper pairs. The bizarre physical properties to be expected of such a system were discussed in considerable detail by Khalatnikov in his invited address (Khalatnikov, Mineev and Volovick

Proc. 14th. Inf. Conf. on Low Temp. Phys, North Holland Pub. Co., Amsterdam, **5**, 102, 1975) to the recept LT14 conference in Helsinki—but he was careful to avoid alluding to any numbers. In particular, he did not make any mention of a value for T_c

Patton and Zaringhalam have now described a theory which, with one adjustable parameter, gives a reasonable description of the pressure dependence of T_c for pure ^{3}He. They fix this parameter by fitting their theory to the experimental results already obtained and then, together with a variety of other experimental information, use it to derive a value of T_c for a ^{3}He–^{4}He solution. They conclude that, for a saturated solution of 8.85% ^{3}He in ^{4}He under a pressure of 20 bar, $T_c=0.9$ mK This result is some 10,000 times larger than an earlier prediction by Østgaard (*Phys Lett.*, **94A**, 433; 1974) of ~ 10^{-4} mK.

These calculated values of T_c may be compared with 0.7 mK, the lowest temperature to which pure ^{3}He has so far been cooled Making thermal contact to a ^{3}He–^{4}He solution is rather more difficult then to pure ^{3}He at these temperatures, however, so that cooling a solution below 0.9 mK may not necessarily be quite within present experimental capabilities; but it certainly cannot be far removed.

Remembering the bitter experience of the theoretical T_c values for pure ^{3}He, a certain level of scepticism is inevitable in relation to Patton and Zaringhalam's 0.9 mK It is nonetheless encouraging, and we should not have to wait very long for their prediction to be put to the test in an actual experiment. ☐

No need for glycophorin?

from a Correspondent

IT is a truism that any breakthrough in science, as in art, fashion or sport, quickly becomes a commonplace Nowhere is this more obvious than in protein sequencing However, although the complete sequencing of a protein no longer has, perhaps quite the same impact as previously, the sequencing of a membrane protein is still a relatively rare occurrence This has been achieved recently for glycophorin, a major protein of the human erythrocyte membrane (Tomita and Marchesi, *Proc natn Acad Sci. U.S A.*, **72**, 2964–2968, 1975; see *News and Views*, **258**, 478; 1975) Some of the sequence is familiar from earlier publications by Marchesi and his colleagues. In particular the now famous sequence of 23 amino acids lacking charged residues and enriched in hydrophobic residues such as leucine, isoleucine and valine, is placed firmly towards the carboxyl terminal of the polypeptide chain. This sequence is thought to be responsible for integrating the protein into the hydrophobic environment of the membrane. A segment of the polypeptide chain at the carboxyl end is believed to protrude internally whereas the amino terminal sequence, bearing a large amount of carbohydrate, is on the outer side of the membrane.

The function of this quantitatively important constituent of the erythrocyte membrane is unknown. Some recent results suggest that it may be dispensed with altogether without undue effect on the survival either of the erythrocyte or of the person carrying these cells.

The starting point for this work was the identification of a rare genetic variant in humans which affects erythrocyte surface antigens. The En^a antigen is present on the surface of almost all human erythrocytes except in some very rare individuals. Three families are known with this trait: two in Finland and one in England (Dainborough *et al., Vox Sang.*, **17**, 241–255; 1969; Furuhjelm, *et al., Vox Sang*, **24**, 545–549; 1973) These individuals, who are clinically normal, also show unusually weak activity of another common erythrocyte antigenic system called MN. It has been known for many years that MN antigenicity is associated with glycophorin and this prompted Tanner and Anstee (*Biochem. J.*, **153**, 271–277; 1976) to look for this component in En(a–) erythrocytes. It turns out that the erythrocytes apparently lack glycophorin completely. Erythrocyte En(a–) membranes analysed by SDS polyacrylamide gel electrophoresis have normal peptide composition except for the loss of glycophorin and a minor glycoprotein species of slightly smaller molecular weight.

Tanner and Anstee then tried to label glycophorin in En(a–) erythrocytes with lactoperoxides. In normal erythrocytes, glycophorin and another membrane protein are readily iodinated by this means. In En(a–) erythrocytes however, only one membrane component was labelled and this was not glycophorin.

What these results imply, therefore, is that glycophorin itself is not absolutely required for the function of the erythrocyte This is surprising on two counts; first, glycophorin is one of the two most abundant proteins of the erythrocyte membrane Together with a component called protein 3 it accounts for almost half of the membrane proteins. Second, there is considerable evidence that glycophorin and protein 3 form a non-covalent complex in the membrane. It has been suggested (see Rothstein *et al., Fedn Proc.*, **35**, 3–10; 1976) that the complex plays a coordinated role in anion transport Although protein 3 appears to be the more directly involved in anion transport, it will be interesting to see if the quite drastic changes in the composition of membrane protein of En(a–) erythrocytes result in any physiological effects on ion transport. ☐

Aspects of tumour biology

from M. J. Bevan and I. S. Trowbridge

The Armand Hammer Symposium in Tumour Biology was held at The Salk Institute, San Diego in January 1976.

THE origin of the cancer cell and its interaction with the immune system were the main themes of the Symposium.

In the opening session, David Baltimore (Massachusetts Institute of Technology) and Charles Heidelberger (McArdle Laboratory, Madison) discussed viral and chemical oncogenesis respectively. Baltimore showed that the resistance to infection by N-tropic or B-tropic murine leukaemia viruses conferred by the FV-1 locus is probably at the level of transcription implying that FV-1 is a regulatory gene coding for a repressor. Viral DNA could be made and integrated into the genome of resistant host cells but unlike the case of sensitive host cells virtually no viral RNA was produced. He also described the *in vitro* transformation of murine bone marrow and foetal liver cells by Abelson Leukaemia virus and its quantitation by a focal assay. Whether the target cell for transformation is a pre-B cell or a more primitive stem cell and how many such cells are present in the various haemopoietic organs is uncertain. It seemed unlikely that a B-cell itself is the target as no immunoglobulin-bearing cells were transformed.

Heidelberger established that chemical carcinogens actually transform normal cells rather than select pre-existing malignant cells from within the population of "normal" cells in his *in vitro* fibroblast cultures, by showing that frequencies of transformation greater than 50% are possible. He also described evidence that chemical carcinogens do not cause transformation by activating endogenous RNA tumour viruses. One importance of his experimental system is that it provides a screening procedure for potential carcinogens. In this regard it was interesting to hear that the effects of promotors, chemicals that do not themselves cause cancer but which potentiate the action of other carcinogens, can also be assayed in this system.

George Klein (Karolinska Institute, Stockholm) described the interaction of Epstein-Barr virus with human B lymphocytes. He described convincing evidence for the identity of EB virus receptor and the complement receptor of B cells stressing however that not all complement receptors bind the virus. He also showed experiments with EB virus-negative B cell lines and their *in vitro* transformed sublines which illustrated the selective *in vitro* growth advantage that transformation with EB virus confers on the transformed cell.

Gerald Edelman (Rockefeller University, New York), suggested that it may be possible to bring together some of the diverse changes which take place when a cell is transformed by considering the role submembranous microtubule assemblies have in maintaining cell morphology and transmitting extracellular growth signals to the cell interior.

Many tumours express cell surface structures which can be recognised as foreign by the immune system of the host. Ways in which genes in the major histocompatibility complex may control immune responsiveness were a major theme. J Klein (University of Texas, Dallas) showed partial amino-acid sequence data from four laboratories on various alleles of the 45,000 molecular weight H-2K and H-2D major histocompatibility antigens of the mouse. Comparison of the sequences of different alleles of one locus shows multiple amino acid replacements—30–40% of the positions are different. These are "complex allotypes" in Lee Hood's terminology though Klein warned that comparing products of other alleles with the H-2^{b} antigens could be misleading since this haplotype may have come from a different subspecies or different species of mouse than that from which other inbred strains were derived Comparison of the sequences of the products of the K and D loci again shows 20–40% amino acid substitutions Here the remarkable thing is the degree of similarity between their products, confirming their origin by gene duplication. The K and D sequences of the mouse appear more similar to each other than to either the human HLA-A or HLA-B sequences, that is, species-specific residues are shared by K and D. This raises the possibility that the two loci, K and D in mice and HLA-A and HLA-B in humans separated in evolution after divergence of the species.

What does this have to do with immune responsiveness? These gene products control interactions between cytotoxic effector T cells and target cells. Doherty and Zinkernagel have suggested that neoantigens (including tumour-associated antigens) are recognised only in association with K and D products as complex determinants (the altered-self hypothesis). Klein favoured the idea that the K and D restriction of cytotoxicity is explained by two independent interactions. First, the T cell receptor binds the neoantigen which only leads to a successful cytolytic interaction when the associated H-2K or D itself binds the identical K or D molecules on the target cell, a like–like interaction. Edelman felt that this was ruled out by his experiments with Schrader showing that antibody to H-2K and D blocked a cytolytic interaction only when the target (not the killer cell) was treated. He proposed a T-cell receptor with two subsites, one for K or D and the other for neoantigen leaving the origin of the restriction as "altered self".

H. McDevitt (Stanford University, California) described the distribution of H-2 I-region-associated antigens on various T cell populations. Neither precursor cytotoxic T cells, effector cytotoxic T cells, nor helper T cells are removed by treatment with anti-Ia serum and complement. In contrast, suppressor T cell activity in two systems (allotype suppression and suppression of a hapten carrier response) is sensitive to anti-Ia serum and complement. Partly on the basis of these results, McDevitt interprets the helper T cell replacing factor of Taussig and Munro, which is Ia positive and antigen specific, as being a suppressor T cell factor like that described by Tada The factor, according to McDevitt, enhances the IgM response only as a consequence of suppressing the IgG response

Despite this, McDevitt believes that Ir genes which determine high or low responsiveness to particular antigens, are expressed at the helper T cell level, that is, failure to develop helper T cell activity is not due in all cases to excessive suppressor T cell activity. Therefore the Ir gene product expressed in helper T cells is predicted to lack Ia determinants

A. Mitchison (University College London) was concerned with whether two immunogenic but separate molecules on the same cell would be coprocessed by the immune system. Some tumour antigens may be weak because the tumour cell presents no other determinants for associative recognition. He showed that the antibody response to the Thy-1.2 alloantigen could be enhanced by the associative recognition of other H-2 coded or non-H-2 coded alloantigens. Nylon wool purified primed T cells do help the anti-Thy-1.2 response of primed purified B cells and Mitchison has evidence that the T cells and B cells effectively cooperate when recognising different alloantigens on the same immunogenic cell. AKR (H-2^{k}, Thy-1.1) spleen cells which have been primed with CBA thymocytes (H-2^{k}, Thy-1.2) give a good response to CBA thymocytes on transfer into irradiated AKR recipients. B10.BR thymocytes (H-2^{k}, Thy-1.2) also stimulate a good secondary response but B10 (H-2^{b}, Thy-1.2) or F$_1$ (CBA×B10) thymocytes fail to generate a good response. This failure to stimulate cannot be interpreted as meaning that Thy-1 is seen by T cells as a modification of H-2 antigens, that is, as a type of altered-self hypothesis. Mitchison views this as an example of antigenic competition in which recognition of a foreign H-2 somehow removes the Thy-1 antigen (which has to be on the same cell) from the inductive processing system.

Antigen presentation in the response of rats to syngenic chemically induced tumours was a feature of R. Baldwin's talk (University of Nottingham, UK). An animal protected against a tumour by immunisation with irradiated cells shows responsiveness to individually specific tumour antigens. A tumour bearer, on the other hand, responds also to embryonic antigens common to many tumours (as detected in the lymph node microcytotoxicity test). Grafting irradiated tumour cells leads to tumour-specific protective immunity. However, if the host has been pre-exposed to tumour antigen in the form of isolated membrane or 3M KCl extracts then a subsequent graft of irradiated tumour cells does not lead to protective immunity although a humoral response is observed. This raises questions of how the class of the response to a tumour is determined.

Melvin Cohn (The Salk Institute, San Diego) made the interesting comment that all tumours presently used as model systems have already undergone rigorous selection for their ability to escape immunological rejection since they arise in immunocompetent hosts. He suggested that the complexity of tumour rejection may be more easily analysed by establishing tumours in immunoincompetent hosts from the *in vitro* transformed colonies of Heidelberger and studying the way in which these cells escape single step immunological selection pressures such as T cell killing or antibody-dependent cytotoxicity. □

review article

Archaean high grade complexes and modern continental margins

B. F. Windley* & J. V. Smith†

Two kinds of geological terrain formed before 2,500 Myr ago. First, the greenstone belts, which are linear basins full of sediments and volcanics, possibly comparable with the marginal basins that occur behind modern island arcs. Second, and the subject of this paper, are high grade complexes containing rocks that have been deformed and recrystallised at high temperatures and pressures—granitic gneisses derived from granitic rocks are particularly common. Examples occur in north-western Scotland, Greenland, the Labrador coast, the Limpopo Belt in southern Africa, southern India, and probably the Aldan and Kola shields in the USSR. These complexes are so similar lithologically that broad generalisations about their tectonic evolution are justifiable. No major attempt has been made to see if they share any similarities with modern geological environments whose origins are better understood. We suggest that they are ancient analogues of the modern deep seated granitic batholiths located along the main arc axis of active plate margins of North and South America, for example in California and the Andes; accordingly, they are complementary to the greenstone belts in their back-arc setting.

THE tectonic evolution of Archaean high grade gneissic regions is poorly understood, especially the origin of tonalitic–granodioritic gneisses which make up 80–85% of the present surface[1,2]. Various source materials have been proposed, on the basis of chemical analogies; they include andesitic–dacitic volcanic rocks[3–6], modified earlier gneisses[7], dioritic rocks that underplated the crust[8], plutonic granitic rocks in general[1,9,10], and igneous tonalites and granodiorites[11]. Some local chronologies are known[9,10,11], but little is understood of their evolutionary meaning.

We propose a more general approach in which all the tectonic and chemical interrelations of the Archaean rock types are compared with properties of rocks in Mesozoic and Cainozoic fold belts, whose tectonic environments are better understood. Specifically, we suggest that Archaean quartzofeldspathic gneisses and their enclosed remnants of layered igneous complexes[12] and supracrustal rocks are metamorphosed and deformed equivalents of calc-alkaline batholiths in the Cordilleran Fold Belt of western North America, and probably of the similarly active plate margin of the Caledonian Fold Belt of Britain. A strict uniformitarian comparison cannot be expected because, first, the older rocks show indications of metasomatism, second, mineralogical reactions have occurred which indicate burial of some of the Archaean rocks to 20–30 km; third, earlier plates may be smaller, less coherent and more mobile than modern plates, resulting in a different tectonic style at continental margins, and fourth, early magmas produced by partial melting of the lower crust and upper mantle may differ chemically from modern ones Even at the risk of oversimplification, however, we have made the comparisons in order to provide ideas to be tested by further mineralogical, petrological and geochemical studies

Archaean relationships

The Archaean high grade regions, to which this model is most readily applicable, are north-western Scotland (the Scourian)[13], Greenland[1,10], Labrador[14], the Limpopo Belt of southern Africa[15], and southern India[16].

Gneisses formed at least twice in Greenland and Labrador, and only the younger are relevant here. In the other regions only the younger gneisses have been recognised so far. The relevant chronology is [1,9,10,14]:

Oldest	Formation of gneissic basement
	Deposition of supracrustal rocks (basic volcanics, pelitic schists and gneisses, marbles and quartzites)
	Interthrusting of supracrustals and basement
	Intrusion of layered ultramafic–gabbroic–anorthositic complexes
	Intrusion of tonalite–granodiorite
Youngest	Deformation and metamorphism of tonalite–granodiorite to give rise to high grade gneisses.

The Greenland gneisses grade into homogeneous 'granitic' rocks in low-deformation zones[9], and Labrador gneisses occur as deformed veins of intrusive 'granite'[11]. Gneisses in all regions have calc-alkaline affinities whether metamorphosed to amphibolite or granulite grade Accepting the arguments against a volcanic origin[8], we prefer to envisage a suite of tonalitic–granodioritic rocks as the precursor of the quartzofeldspathic orthogneisses[1]. The chemistry of major and trace elements in the gneisses compares best with that of 'granitic' rocks from

modern continental margins[11], and the very low initial ratios of strontium isotopes (about 0.701) are consistent with direct derivation from the mantle[17].

Metamorphosed remnants of layered igneous complexes with an idealised upward stratigraphy of ultramafic–gabbro–anorthosite[12] occur within the gneisses. The complexes are bordered either by supracrustal rocks into which they were intruded[18] or directly by the gneisses[19]. Parts of the Fiskenaesset Complex, western Greenland, are associated with supracrustals rocks[20], and other parts are not[19]. The intrusion of the complexes was followed immediately by that of the 'granitic' rocks[9,10,14], resulting in the complexes occurring as giant rafts in vast quantities of 'granitic' rocks: thus all the Fiskenaesset gneisses, accounting for 84% of the present surface area[2], are younger than the Fiskenaesset layered complex[21]. Even where some older gneisses predate the complexes, as near Godthaab, western Greenland, the younger gneisses may account for over half the area[9]. Apparently the most highly developed gneisses coincide with the most highly developed layered complexes (for example, at Fiskenaesset).

The complexes are in all stages of fragmentation. In places, individual layers persist for many kilometres (for example, Fiskenaesset, Limpopo), but the complexes commonly occur as isolated lenses and pods from kilometre to metre size (southern India[22], western Greenland[23], Scourian[13]). Although late deformation was responsible for local folding, thinning and boudinage of some layers, it would seem an unlikely cause of the fragmentation of the complexes into the millions of small pods and lenses found in many areas. Perhaps this fragmentation was connected with the engulfment of the complexes by granitic material on an enormous scale. Explosive mechanisms may have been involved, and a detailed comparison of the Archaean occurrences with the appinitic rocks and breccias of the Caledonian mountain chain, especially in Donegal, is desirable[10].

Comparison with oceanic crust

Archaean sediments, volcanics and layered complexes have been interpreted as representing a section through oceanic crust[24]. Graphitic pelites and marbles have been correlated with modern pelagic sediments leading to the interpretation of quartzites and psammites as recrystallised oceanic cherts; the occurrence of dolomitic limestones at the Mid-Atlantic Ridge has also been noted. Amphibolites with occasional relict pillows have been matched with oceanic basic volcanics, and the anorthosite–leucogabbro–ultramafic sequence has been related to layered igneous complexes of the type inferred to occur under some modern oceanic basalts[25].

Objections can, however, be raised. Where the Archaean quartzites are best developed, as in the Limpopo Belt, they are current-bedded and thus interpreted as orthoquartzites (R. M. Shackleton, personal communication). The carbonate (dolomitic marble)–orthoquartzite–K-rich pelite (sillimanite mica schist) association, typical of most high grade regions, is best explained by deposition in a shallow-water, continental margin[26,27]. Comparison of the chemistry of amphibolites with that of volcanic rocks is fraught with difficulties because of chemical changes undergone during metamorphism[28]. Some Archaean amphibolites have chemical patterns similar to those of modern island-arc volcanics (B. E Leake and B. F. W., unpublished) and others to oceanic volcanics[29]. To distinguish the latter from the early tholeiitic series of island arcs is difficult, especially after metamorphism[30]. Anyway, low-K tholeiites occur in various tectonic environments, and distinction between oceanic and island-arc or continental volcanic rocks, so demonstrable in modern times, should be less apparent in the Archaean[31] Grab samples indicate that layered igneous complexes in modern oceanic crust apparently comprise predominantly Ti, Fe-rich gabbro, and contain only about 5% Cr-poor labradorite anorthosite and gabbroic anorthosite (leucogabbro)[25]. Archaean complexes are very different in both rock proportions and chemistry; thus gabbros are minor and not enriched in Ti and Fe, whereas the bulk of the bodies consist of bytownite–anorthosite and leucogabbro (where best preserved), often interlayered with chromitite Alpine-type ophiolite complexes derived from the oceanic crust are distinguished by a scarcity of the cumulate features characteristic of gravity settling, whereas many Archaean complexes contain chromitites, plagioclase cumulates and crystal-graded layers. Volcanic and plutonic rocks formed at mid-ocean ridges should be characterised by highly variable age relations, stratigraphic succession and distribution (J. Cann, personal communication), whereas Archaean rocks, especially in western Greenland and Limpopo, are noted for remarkable stratigraphic regularity and persistence along strike for tens of kilometres. Only a little acidic tonalite can be generated by one-stage fractionation of ultrabasic mantle.

We believe that these differences between recent oceanic rocks and Archaean complexes are so great that the latter cannot be slices of oceanic crust.

Comparison with Cordilleran fold belts

The Mesozoic batholiths along the axis of the Cordilleran fold belts of North and South America represent the roots of magmatic arcs related to palaeosubduction zones. The most abundant rocks are tonalite, granodiorite and quartz monzonite (adamellite)[32]. The content of K_2O generally increases away from the Pacific margin[33] although potassic granites are a minor component of the batholiths[34].

Within the Peninsular Range batholith of southern California, layered igneous complexes composed largely of calcic plagioclase and primary amphibole include a succession of minor peridotite and troctolite and predominant hornblende anorthositic gabbro[35]. The mineralogy and chemistry of these rocks is similar to that of the Archaean complexes. The California complexes have been interpreted as early cumulates of a hydrous and refractory nature precipitated from a basaltic–andesitic magma which later yielded the calc-alkaline batholithic suite.

Concentrically-zoned ultramafic complexes of the Alaskan type are clearly distinguishable from the alpine-type ultramafic complexes usually considered to be obducted oceanic crust and mantle. The Alaskan-type complexes, which also occur in the Ural Mountains, British Columbia, Venezuela and perhaps Japan, have been interpreted as the products of fractional crystallisation and flow differentiation of basaltic magma in deep-seated, volcano feeder pipes[36]. Crystallisation under hydrous conditions in the pressure range 2–11 kbar has been invoked to explain the presence of magnetite and hornblende as well as olivine, clinopyroxene and plagioclase. The associated eruptive products are andesites and probably aluminium-rich tholeiitic basalts.

Although few detailed mineralogic–petrologic studies have been undertaken, it is certain that calc-alkaline volcanic and plutonic rocks are linked with the hydrous, amphibole-bearing intrusions, typically developed along modern continental margins.

Many of the layered complexes within the Peninsular Range tonalitic batholith are bordered by a group of sediments (the Julian Schists) that comprise sillimanite mica schists (meta-K pelites), quartzites and carbonate rocks, an assemblage that is strikingly similar to that in the Archaean tonalitic gneisses and that likewise formed in a shelf–continental margin environment.

In the Dawros–Cashel area of Connemara, several fragmented layered complexes[37] with peridotite[38,39] and hornblende–calcic plagioclase gabbro grade upwards into plagioclase gneiss[40]. According to a plate tectonic model[41], this area lies on the northern continental margin of the Caledonian Fold Belt. We suggest that the petrochemical features of these bodies render them comparable to the Archaean and California examples. Particularly important is the generally accepted evidence of major horizontal movements—now represented by the extensive occurrence of nappes—together with the regional metamorphism to garnet and kyanite grades in the Dalradian rocks of Scotland[42]. These features occur in the high grade Archaean complexes[10], and apparently represent the final stage of tectonic activity at an active continental margin.

Mineralogical–petrological–chemical considerations

The mineralogy and petrology of the Archaean complexes is interpreted as the result of igneous crystal–liquid differentiation combined with deformation and regional metamorphism. The Fiskenaesset Complex provides the clearest evidence. Co-ordination of folded fragments has revealed seven major zones. From bottom to top they are: minor, magnetite-rich ultramafic rocks; leucogabbro with anorthosite laminae; gabbro; leucogabbro with marked cumulate texture; anorthosite; chromitite; and garnet anorthosite[20,43]. Hornblende occurs in all of the rock types. This sequence has been interpreted as the result of gravity differentiation of a water-rich basaltic magma in which the early crystallisation of Mg–Al–Ti–Cr–magnetite and the continued precipitation of primary magnesio- to tschermakitic-hornblende led to a trend quite different from that found in dry, layered basaltic complexes such as Skaergaard. Some megacrysts may locally represent original primocrysts, but most rocks have metamorphic textures superimposed on modal variations retained from the original igneous layering. Related structural and mineralogical evidence has been found in the Sittampundi (ref. 44 and B. F. W. and J V. S., unpublished), Limpopo[18] and Lewisian complexes[45], but the data are less complete for various reasons. Solid-state recrystallisation has modified mineral compositions in all of the complexes, and metasomatism has changed some bulk compositions.

Although estimates of the temperatures and pressures reached during metamorphism depend on somewhat controversial thermodynamic models and experimental phase equilibria, metamorphism of the Archaean high grade complexes certainly occurred at depths estimated at between 15 and 40 km. In South Harris, chemical relationships between garnet, pyroxenes and olivine indicate that granulite metamorphism occurred near 800–860 °C and 10–13 kbar (ref. 46). Garnet-clinopyroxene rocks from Sittampundi reacted near 850 °C and 7–8 kbar (ref. 47). Also at Sittampundi, the coexistence of staurolite, kyanite, garnet and other minerals in one hand specimen indicates conditions near 600 °C and over 5 kbar, whereas the occurrence of sillimanite-bearing assemblages indicates somewhat different conditions (B. F. W. and J. V. S., unpublished). Olivine and plagioclase grains have not been found together in a single hand specimen from Fiskenaesset, and they may have been replaced by spinel, pyroxene and amphibole. Adjacent grains of orthopyroxene and plagioclase coexist in some Fiskenaesset rocks without having reacted to garnet and quartz. Chemical relationships between finely intergrown oxide minerals (B. F. W., J. V S., I. M. Steele and F. C. Bishop, unpublished) indicate equilibration down to 300–600 °C, and those between intergrown sulphide minerals (F. C. Bishop, J. V. S. and B. F. W., unpublished) indicate equilibration down to 100–200 °C. The metamorphic history differs from one complex to another, from one part to another, from one mineral assemblage to another, and from one grain to another. In spite of the local idiosyncrasies, which depend on relative diffusion coefficients and stresses, there are overall large scale effects interpretable in terms of high grade regional metamorphism which must have affected the tonalite–granodiorite gneisses as well as the igneous complexes.

The extent of metasomatism is uncertain. In the Fiskenaesset Complex, mineral compositions vary monotonically with position[43], and erratic metasomatism should be insignificant except perhaps for minor development of mica and sodic plagioclase and of some minerals of the contact facies[20]. In the Limpopo Complex, one traverse showed strong erratic plagioclase zoning to more sodic compositions, whereas compositions were steady in another traverse[18] A major question is whether most of the amphibole in the Fiskenaesset Complex crystallised from the igneous magma or whether it is a metasomatic product after pyroxene. In some thin sections, amphibole occurs around pyroxene grains, but the intimate interlayering of amphibole-free and amphibole-bearing assemblages in many felsic and mafic rocks suggests an igneous origin before metamorphic recrystallisation. Although small composition differences between amphiboles from felsic and mafic parts of the same zone[43] probably result from metamorphic equilibration, the generally tschermakitic-pargasitic nature of all the amphiboles is like that of amphiboles produced synthetically from hydrous basaltic melts (see, for example, refs 48–51). Furthermore, tschermakitic-pargasitic hornblendes occur in modern unmetamorphosed rocks where the texture is consistent with the crystallisation of amphibole from a magma (see refs 52–54). Rare symplectites of spinel and pyroxene may result from the dehydration of amphibole[20]. Although much further study is needed, especially of relatively undeformed specimens from low deformation zones, we assume here that amphibole is one of the igneous minerals at Fiskenaesset, and that the magma was hydrous.

Magnetite occurs as dust in some mafic silicates at Fiskenaesset, but most magnetite of the lowest zone occurs as discrete Cr-rich grains whose association with ilmenite and Mg–Al spinel can be interpreted as the result of metamorphic decomposition of primary, Mg–Al–Cr–Ti-bearing magnetite (I. M. Steele, F. C. Bishop, B. F. W and J. V. S., unpublished). Its occurrence throughout the complex as a primary phase, especially in the early mafic zone, would explain why there is no strong trend towards iron enrichment. The primary precipitation of magnetite requires redox conditions more oxidising than those within dry basaltic layered complexes[55], and redox conditions for the Fiskenaesset magma could be inferred by reference to phase relationships in basaltic melts[56] Chromium-bearing spinel, loosely called chromite, occurs in many Archaean complexes. Its composition range—atomic Mg/(Mg+Fe) 0–0.4; Cr/(Cr+Al) 0.2–0.6—distinguishes it from Cr-spinels in alpine-type, concentric-Alaskan, and dry-basaltic layered complexes (ref. 18, and J. V. S. *et al.*, unpublished). The compositional adjustment of cumulus Cr-rich spinels by reaction with silicates and trapped liquid has been demonstrated in the Rhum layered intrusion[57]. No zoning was detected in any Fiskenaesset chromites in spite of considerable textural variation, and the general compositional features are independent of the modal proportion of Cr-spinel to silicates. Particularly noticeable is the absence of Cr-spinel in most, but not all, of the lowest ultramafic zone at Fiskenaesset, and its principal occurrence as thin layers between late anorthosites. Many basaltic intrusions have early chromite and late magnetite. The near-absence of early chromite at Fiskenaesset can be explained by the precipitation of Mg–Al–Cr–Ti-magnetite as a result of a relatively high state of oxidation.

Archaean high grade complexes carry highly calcic plagioclase (Fiskenaesset, mostly An_{96-80} (ref. 43); Limpopo, up to An_{75-80} (ref. 18); Sittampundi, up to An_{100} (ref. 44, and J. V. S. *et al.*, unpublished)) which distinguishes them from Proterozoic anorthositic complexes carrying labradorite and andesine. Even the latest plagioclase at Fiskenaesset is highly calcic (An^{80}), and there is no trend to very sodic or even potassic feldspars, as in many differentiated basalts. As proposed for the ultrabasic and basic intrusions of Connemara[37], the most obvious explanation for the persistently high Ca content of Fiskenaesset plagioclase is the continued depletion of Na and K from the wet residual magma by precipitation of primary hornblende with $\sim 2\%$ Na_2O, $\sim 0.4\%$ K_2O and $\sim 12\%$ CaO. Calcium-rich pyroxenes from dry basaltic complexes carry $<1\%$ Na_2O, $<0.2\%$ K_2O and $\sim 18\%$ CaO, whereas Ca-poor pyroxenes carry hardly any Na_2O and K_2O, thereby permitting the concentration of Na and K into later plagioclase.

In spite of all the uncertainties caused by regional metamorphism and deformation, the major mineralogical features of the Fiskenaesset complex seem to be qualitatively consistent with the crystal–liquid differentiation of a wet, oxidised, basaltic magma in a closed magma chamber. Detailed experimental syntheses along the lines of those already carried out on basaltic and ultrabasic compositions (refs 48–50, and 58–61), followed by subsolidus equilibration, are needed to provide detailed reference data. In the meantime, it is necessary to rely on qualitative and semiquantitative features (the early precipitation of Mg–Al–Ti–Cr-magnetite; late crystallisation of highly calcic plagioclase and high-Fe, medium-Cr spinel; prolonged crystallisation of tschermakitic–magnesio-hornblende; medium Fe/Mg ratio of ferromagnesian minerals) in looking for possible matches to the Fiskenaesset Complex in modern environments. To set the search in the widest context, modern rocks with highly calcic plagioclase need to be examined, and their wider mineral contents should be checked against the Fiskenaesset Complex.

A nodule from alkali-olivine basalt, Auckland, New Zealand, contains 74% An_{97} (ref 62). Ultramafic nodules in basalts from Hawaii and Itinome-gata, Japan, carry minor plagioclase ranging up to An_{90} (refs 63 and 64). Associated minerals are too highly magnesian to match those at Fiskenaesset. Some basalts from oceanic environments carry megacrysts or phenocrysts of composition An_{70-89} (refs 65–67), but the differentiation trend in these near-surface flows is quite unlike that in Archaean complexes. The younger volcanic rocks of Tonga, and the Cape Hoskins volcanic rocks, Papua, contain An_{80-90} phenocrysts[68,69], but titanomagnetite occurs only in the late differentiates; amphibole is absent.

In the Antilles Island Arc, phenocrysts up to An_{85} occur in andesite and basalt from Montserrat, along with amphibole-plagioclase (An_{93-89})-magnetite xenoliths[70]. At Soufrière Volcano, St Vincent, ejected plutonic blocks contain plagioclase (An_{96-89}), olivine (Fo_{79-67}), salite, hastingsitic amphibole and Mg–Al–Ti-magnetite[71]. The Soufrière amphibole has too little SiO_2, the magnetite has no detectable Cr, and the salite has too much Al_2O_3 to match the Fiskenaesset minerals. The Salt Lick Creek layered intrusion of Western Australia[72] contains plagioclase (An_{84}) associated with olivine (Fo_{81-84}), orthopyroxene (Fs_{15-20}), clinopyroxene ($Wo_{48-44}En_{46-48}Fs_{6-8}$) and Mg–Al-chromite, in assemblages similar to those in layered complexes in Rhum[73], the Cuillins of Skye[74], and Mull[75]. The absence of amphibole and magnetite distinguishes this suite from the Fiskenaesset Complex. Megacrysts of An_{87-93} with inclusions of augite or perhaps augite plus amphibole occur in feldspathic dykes of allivalite composition in Skye[76], and ultrabasic breccias in the Rhum Complex[54] contain plagioclase (An_{87-97}), olivine (Fo_{83-82}), augite ($Wo_{43-46}En_{46-48}Fs_{8-9}$: 4 weight % Al_2O_3), primary kaersutite (TiO_2, 4.9; Al_2O_3, 11.6; Cr_2O_3, 0.5; FeO, 8.2; CaO, 11.9; Na_2O, 2.6; K_2O, 1.0 weight %), phlogopite, Mg–Al–Ti chromite–magnetite and picroilmenite. Although the amphibole is too high in TiO_2 and low in SiO_2 and the augite is too rich in Al_2O_3, this mineral assemblage might resemble selected assemblages in the Fiskenaesset Complex after metamorphism of the former at about 5 kbar and 900 °C. The Greenhills Ultramafic Complex of New Zealand[77], ranges from chromite-bearing dunite to wehrlite, gabbro and allivalite, all three of which carry titanomagnetite and brown hornblende. The sequence of the opaque minerals provides a ready distinction from the Fiskenaesset Complex, but major-element compositions of the olivine, pyroxene and plagioclase (An_{88-92}) lie in the Fiskenaesset ranges

Alpine-type ultramafic complexes[78] can be dismissed because their olivines and orthopyroxenes are too magnesian rich (mg near 0.9) to match the range (0.86–0.74) for the Fiskenaesset Complex. Concentrically-zoned ultramafic complexes of Alaskan type[52,78,79] contain rocks with various amounts of primary hornblende, olivine, clinopyroxene, magnetite, chromite, ilmenite and hercynite spinel with compositions fairly similar to those of the Fiskenaesset minerals; but plagioclase is virtually absent except in late hornblende-plagioclase pegmatite, and the type of zoning differs from that at Fiskenaesset. The interpretation[36] of these zoned complexes as feeder pipes of andesitic volcanoes is feasible, and the resemblance of their mineral compositions to those at Fiskenaesset could be attributable to the crystallisation of a hydrous basaltic magma in both cases, one being open and the other closed Layered gabbroic and ultramafic rocks in a tectonic melange on the Kodiak islands of Alaska have received only a brief description[80], but they should be compared closely with Archaean complexes Ultramafic rocks at Emigrant Gap, California[81], are part of a mafic complex showing near-concentric zoning from dominant wehrlitic peridotite in the core to tonalite in the rim. Olivine, pyroxenes and plagioclase from the inner rocks lie in the composition range of the Fiskenaesset rocks. Magnetite is ubiquitous and chromite also occurs, but no compositions have been determined. Amphibole is absent in many rocks though it occasionally replaces augite. Detailed chemical studies are needed, but the differentiation trend to tonalite apparently results because the water content was too low to produce substantial amounts of amphibole.

The Fiskenaesset Complex fits best with the numerous bodies (~ 100) of peridotite-gabbro of up to 70 square kilometres in outcrop dispersed among the larger tonalite–granodiorite bodies of the Peninsular Range Batholith of southern California[82,83]. The mineral assemblages and compositions of the peridotites, gabbros and anorthositic gabbros[35] can be matched with those at Fiskenaesset except for small details, and the interpretation in terms of the differentiation of a wet basaltic–andesitic magma is similar. The differences between the two mineralogies are explicable in terms of different degrees of metamorphism and small variations in the differentiation trend resulting from small changes of water pressure, oxidation state, and so on.

Although more detailed mineralogical–petrological–geochemical studies are needed of layered complexes in Archaean and modern environments, our survey indicates that, first, Archaean complexes can be explained by the metamorphism of igneous complexes developed from wet basaltic magmas differentiating under oxidising conditions, and, second, the Archaean complexes can be matched chemically with the complexes in the southern California batholith. Mineralogical data for the layered complexes of the Caledonide fold belt of Ireland and Scotland are sparse (refs 37–39, 84 and 85) but the presence of calcic plagioclase, apparently primary hornblende, and medium-Cr, medium-Fe spinel are tantalising clues.

Discussion

The crux of our argument is that the late Archaean intrusive tonalites (now tonalitic gneisses and granulites) differentiated from a more basic, mantle-derived magma generated in some type of active continental margin. We suggest that enclosed, layered igneous complexes can be matched mineralogically with complexes enclosed within a tonalitic batholith of western North America, and that the associated Archaean and Mesozoic orthoquartzite-carbonate-K-pelite associations are both typical of a shallow-water continental margin. Furthermore, our argument that the Archaean high grade regions are equivalent to the deep-seated levels of modern arcs is consistent with the current interpretation of greenstone belts as fossil back-arc marginal basins[86,87].

Because Archaean tectonic conditions and magma compositions may differ from present ones, analogies must not be pressed too far. Whereas the granitic diapirs and vertical, near-cylindrical, zoned complexes of the Alaskan type reflect vertical transport in modern continental margins, strong arguments favour horizontal tectonics in the Archaean[10]. The apparently greater abundance of komatiitic lavas in Archaean times can be explained by a steeper geothermal gradient resulting from higher heat production by younger radioactive species. Early basaltic magmas may have been wetter than younger ones because the Earth was undergoing strong outgassing in the Archaean (see, for example, ref 88). Early plates may have been smaller, less coherent and more mobile Nevertheless, we suggest that the growth of continents in the late Archaean can be studied profitably in the context of models related to accretion at the leading edge of modern continental plates.

Observation of light emission from a rhodopsin

Aaron Lewis, John P. Spoonhower & Gregory J. Perreault

School of Applied and Engineering Physics, Cornell University, Ithaca, New York 14853

Radiative emission has been observed from the retinylidene chromophore of bacteriorhodopsin, the purple membrane protein of Halobacterium halobium.

LIGHT emission has never been observed from the retinylidene chromophore of any rhodopsin[1]. In addition, no vibronic structure has been detected in the absorption spectrum of the chromophore of rhodopsin or of any isomer of retinal. Furthermore, no reproducible electron paramagnetic resonance signal has been recorded from any rhodopsin. These are the principal reasons why little is known about the electronic structure of the retinylidene chromophore of rhodopsin.

Theoretical calculations[2] and studies of model polyenes[3,4] have been the principal approaches used to try to understand the electronic structure of various rhodopsins. We report here the first observation of light emission attributable to the retinylidene chromophore of a rhodopsin. This study and several other investigations in progress in our laboratory are directed toward resolving the excited state ordering in the retinylidene chromophore and understanding changes in these excited states after a photon interacts with rhodopsin.

Emission spectroscopy of rhodopsin

While applying resonance Raman spectroscopy to study the ground state vibrational structure of the retinylidene chromophore of several rhodopsins and their intermediates[5–10], we

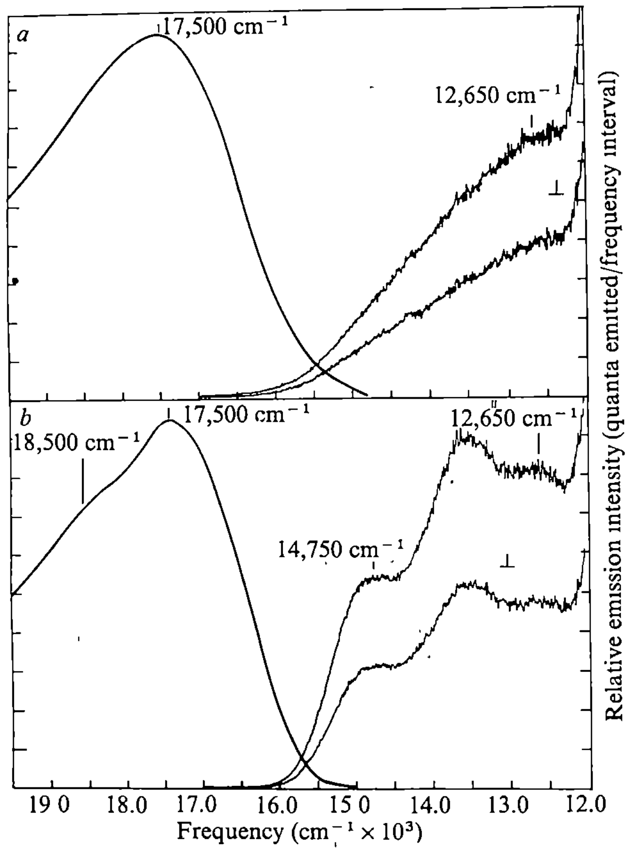

Fig. 1 *a*, Room temperature relative absorbance in arbitrary units scaled from ref. 21 and room temperature relative emission intensity, corrected for instrument response in units of number of quanta emitted per unit frequency interval. The ordinate scale is in thousands of wave numbers. The excitation source for the emission is the 514.5-nm line of an argon ion laser and intensities both parallel and perpendicular to the incident laser polarisation are shown. The apparent rapid rise in the extreme low energy portion of the corrected spectra is artificial and due to division of a nearly constant dark count for the photomultiplier by the vanishing instrument response function. *b*, Low temperature (77 K) relative absorbance in arbitrary units scaled from ref. 21 and 77 K emission intensity corrected for instrument response in units of number of quanta emitted per unit frequency interval. The ordinate scale is in thousands of wavenumbers. The excitation source for the emission is the 580.0-nm line of a CW rhodamine 6G dye laser Intensities both parallel and perpendicular to the incident laser polarisation are shown.

have developed, as a by-product, a spectrometer which is also a sensitive fluorimeter The excitation source for our spectrometer is a tunable dye laser, which provides an ideal source for the stimulation of weak emissions.

We have used our Raman spectrometer to detect emission from rhodopsins and have observed re-emission from bacteriorhodopsin. Bacteriorhodopsin has been studied by Stoeckenius *et al.*[11–14], who have shown that *Halobacterium halobium* uses this rhodopsin to convert light energy into chemical energy. Bacteriorhodopsin has an absorption maximum at 570 nm, and when the retinylidene chromophore is extracted from this species it has an all-*trans* conformation[15]. Bacteriorhodopsin occurs in purple membrane patches in the plasma membrane of the bacteria. These patches can be isolated as membrane fragments which contain the rhodopsin in a crystalline hexagonal array, as shown by diffraction experiments[12,16] The array of rhodopsins is in clusters of three in the membrane with a threefold axis of symmetry perpendicular to the plane of the membrane at the centre of each cluster[16]. We have used bacteriorhodopsin prepared by the procedure of Oesterhelt and Stoeckenius[17]. The membrane fragments were suspended in water at room temperature and in a glycerol–water glass at 77 K. Similar results were obtained from membrane fragments isolated from an S-9 mutant of the bacteria, which is believed not to contain carotenoids.

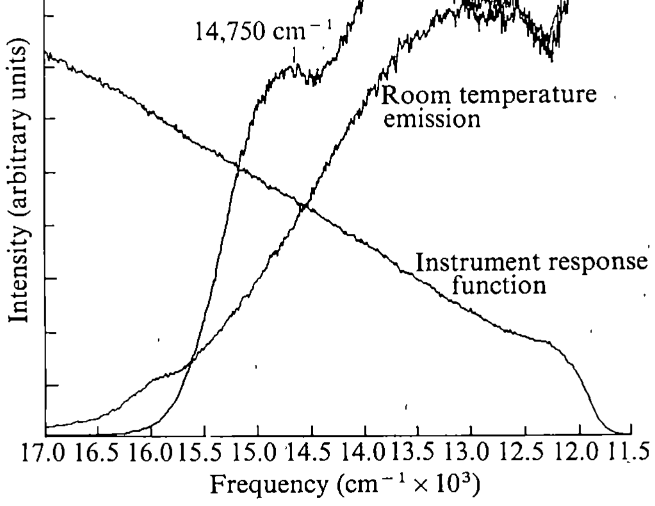
All the spectral data shown in Figs 1–3 were obtained on a laser Raman spectrometer using a red sensitive RCA C31034 photomultiplier with photon counting electronics. Each data point was scaled digitally with the measured instrument response function as determined using a quartz–halogen standard lamp. The instrument response function can be seen in Fig. 2 superimposed on the room temperature and 77 K corrected spectra. The excitation wavelengths used for these measurements were obtained from either an argon ion laser or a continuous wave rhodamine 6G tunable dye laser. All absorption spectra were recorded on a Cary 14 spectrophotometer.

Quantum efficiency

Bacteriorhodopsin is ideal for the study of re-emission from rhodopsins because the membrane fragments contain only one protein[12,16], which is the rhodopsin. The emission maximum we observed at room temperature (Fig. 1*a*) occurs in the near infrared region of the spectrum and is shifted by ~ 4,850 cm^{-1} from the room temperature absorption maximum. There is minimal overlap between the absorption and emission spectra at room temperature and at 77 K. The room temperature quantum efficiency was determined to be between 1.2 (10^{-4}) and 2.5 (10^{-4}), using reduced photosynthetic reaction centres from the bacterium *Rhodopseudomonas spheroides* as a standard, according to the method of Parker and Rees[18]. A quantum efficiency of 1.0 (10^{-3}) was assumed for the reaction centres[19].

Reaction centres are an ideal standard for this study because of their relatively low emission quantum yield and because of the high degree of spectral overlap with the emission of bacteriorhodopsin. Absorbance spectra, taken before and after the measurement of reaction centre emission, indicated no changes in the preparation. The absorbance of bacteriorhodopsin used for the quantum yield was 0.687, while the reaction centres had an absorbance of 0.585. The excitation source for just the quantum efficiency measurements was a quartz–halogen lamp in combination with a Corning 4-96 filter and a broad band 550-nm interference filter. The instrument response function was determined with a lamp having a

Fig. 2 Relative instrument response superimposed on the room temperature and 77 K corrected emission spectra. The emission spectra are in units of number of quanta emitted per unit frequency interval The band observed at approximately 16,000 cm^{-1} in the room temperature emission spectrum is due to the ~3,400-cm^{-1} band in the Raman spectrum of H_2O.



colour temperature of 2,860 K. The spectra were recorded in an analogue mode with a photomultiplier having an S-1 response and were subsequently digitised to allow for a point-by-point subtraction of background due to scatter. Scattering spectra were obtained using a Ludox solution. Furthermore, the spectra were scaled by the instrument response function and corrected to give the integrated area in terms of photons emitted per incident photon. No effect on emission intensity was observed due to deaeration. A detailed study of the quantum efficiency in various conditions will be reported elsewhere.

Polarisation of the emission

The emission intensities of the components parallel and perpendicular to the incident laser polarisation were determined using a Pockels cell to rotate the laser polarisation with respect to a fixed analyser. We recorded the parallel and perpendicular emission components in alternate channels at each frequency setting of the monochromator. The data were separated, scaled and plotted using a digital computer and are presented in Fig. 1*a* and *b*. The emission polarisation$[(I_{||}-I_{\perp})\,(I_{||}+I_{\perp})]$ which we have measured in a 90° scattering geometry varies from 0.23±0.02 to 0.49±0.02 at both room temperature and 77 K when excitation frequencies of 19,436 cm^{-1} and 17,241 cm^{-1} are used. Such variations in the degree of polarisation have been observed for pigments in *Chlorella*, for example[20]. These variations when different experiments are compared result from varying amounts of partial orientation in the gravitational field of the suspension of membrane fragments containing the well-ordered pigment molecules. Because of this effect, one way to determine the degree of emission polarisation accurately is to measure it in the presence of a magnetic field: this is in progress in our laboratory. It is interesting, however, that the degree of polarisation seen in Fig. 1*a* and *b* remains constant throughout the observed emission band within the time scale of any one measurement. Thus these data suggest that the emission emanates from the excited state of a single species.

This conclusion is supported by a plot of the ratio of the intensities of the components at 12,650 cm^{-1}, 13,650 cm^{-1} and 14,750 cm^{-1} in the 77 K spectrum as a function of exciting laser frequency. The data plotted in Fig. 3 are for the exciting laser frequencies which produce the largest changes in the concentration of the photoproduct (unpublished results of R. Lozier and W. Stoeckenius). (The photoproduct at 77 K is a red-shifted intermediate with an absorption maximum ~ 635 nm; refs. 21 and 22). Therefore these experiments also indicate that the components observed in the 77 K spectrum arise from a single species, and this suggests that the components are indeed vibronic fine structure on the emission. The spacing between the components is ~ 1,000 cm^{-1} and ~ 1,100 cm^{-1} in the emission spectrum, and a shoulder is detected at a similar spacing on the high energy side of the 77 K absorption maximum (Fig. 1*b*).

Assignment of observed emission

Light induces photochemical changes in bacteriorhodopsin similar to those observed in all rhodopsins. This photochemical behaviour changes the concentration of rhodopsin with different actinic wavelengths. A two-laser-beam technique can be used to control the photochemical behaviour while observing the emission spectrum. This is particularly feasible at 77 K, where only two components are present, bacteriorhodopsin and the batho form absorbing at ~ 635 nm (refs 22 and 23). These two components are photoreversible at 77 K and exist in a photostationary equilibrium depending on actinic wavelength (unpublished results of R. Lozier and W. Stoeckenius). We have obtained data by the use of two actinic wavelengths. The data are summarised in Table 1. The principal feature of these experiments is similar to the enhancement effects observed in photosynthetic systems, where the effect of two simultaneous actinic irradiations is not equal to the sum of the individual effects[24,25]. The sum of the emission intensities stimulated by 10 mW of illumination at 636.0 nm and by 1 mW of illumination at 514.5 nm obtained in separate experiments is less than the emission observed when the sample is irradiated simultaneously with both beams. In addition, the sum of emissions stimulated with 1 mW of 636.0 nm and 10 mW of 514.5 nm is less than the emission obtained in a single dual beam experiment with the same laser powers and wavelengths. The differences we observed can be explained in terms of changes in the photostationary concentrations of bacteriorhodopsin and the photochemically produced batho form. This is independent of any assumption about the wavelength dependence of the quantum efficiency of the emission and the photochemical quantum yield. The reason for this is that, in the experiments tabulated in Table 1, only the laser powers and not the wavelengths have been changed.

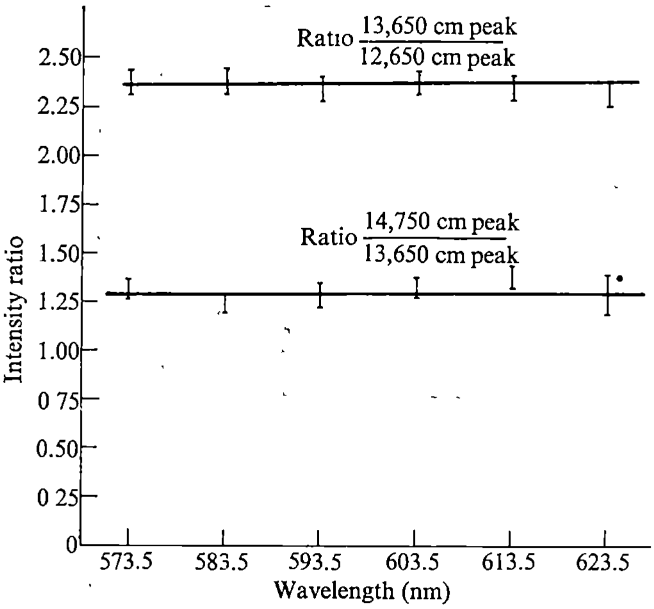


Fig. 3 Ratios of intensities of the bands observed at 14,750 cm^{-1}, 12,650 cm^{-1} and 13,650 cm^{-1} against wavelength. The excitation source is a continuous wave rhodamine 6G dye laser. The ratios shown are calculated from unscaled data

Table 1 is consistent with the interpretation that the primary emitter, in the region we detected the emission spectrum, is bacteriorhodopsin. For example, the addition of 1 mW at 636.0 nm in experiment 6 not only adds its own emission intensity but also increases the steady state concentration of bacteriorhodopsin to a value which is greater than that of experiment 5. Thus the intensity observed in experiment 6 is greater than the sum of the intensities observed in experiments 4 and 5. A similar explanation can be made for experiments 1, 2 and 3.

A comparison of the room temperature and 77 K emission

Table 1 Emission intensities observed using a dual beam technique

Experiment	Laser I (636.0 nm) (mW)	Laser II (514.5 nm) (mW)	Emission intensity proportional to (quanta emitted/incident quanta)	
1	10	0	267	→ 336
2	0	1	69	
3	10	1	386	
4	1	0	26	→ 720
5	0	10	694	
6	1	10	738	

All dual beam experiments make use of both an argon ion laser to produce radiation at 514.5 nm and a CW rhodamine 6G dye laser for 636.0-nm irradiation. The emission intensities have been corrected so that they are given in relative number of quanta emitted per number of incident quanta. Each emission intensity is accurate to ±2%.

spectra (Fig. 3) is also consistent with the suggestion that bacteriorhodopsin is the primary emitter. It is known that, based on the kinetic constant at room temperature for the decay of the batho intermediate to its thermal product[22,23], appreciable concentrations of this intermediate cannot be present at room temperature. Conversely, at the temperature of liquid nitrogen a significant fraction of the photostationary mixture is in the batho form. When this is considered together with the similarities in the room temperature and 77 K spectra, with the observation that the ratio of the vibronic components remains constant at various exciting wavelengths (Fig. 3) and with the results of the two beam experiments, we conclude that the emission emanates from bacteriorhodopsin and that the batho form does not emit in this region of the spectrum. This conclusion is supported by excitation spectra which we have obtained at room temperature.

The excited state

Our experiments indicate that an excited state of bacteriorhodopsin is responsible for the emission spectra we observed. Based on the integrate strength of the absorption for the allowed transition, a radiative lifetime for emission from the ^1B_u state would be 7 ns But measurements of the lifetime by the use of a mode-locked tunable dye laser and by phase-modulation techniques suggest that the calculated intrinsic lifetime of the emission is between 0.1 and 1 μs (our unpublished results with M. Marcus, M Hirsch and A. Kriebel). Thus the emission cannot originate from the ^1B_u state. The observed variation in the lifetime of the emission could result from exciton interactions among the chromophores at high laser intensities.

There is, however, a separation between the absorption and emission bands (Fig 1*a* and *b*) similar to the separation observed by Hudson and Kohler[4] in the spectra of model polyenes, the radiative lifetimes we observe are comparable with those detected by Hudson and Kohler[26] for model polyenes. The data on these model systems have been taken to mean that the lowest energy excited state in these polyenes is a ^1A_g state. The occurrence of such a perfect ^1A_g state, or a perfect ^1B_u allowed state, in the retinylidene chromophore is unlikely especially in view of the large excited state dipoles that are measured (personal communication from R. Mathies and L. Stryer) and the observation of a circular dichroism spectrum in bacteriorhodopsin[27]. Thus our data can only be interpreted to mean that the emission emanates from some state other than the allowed state into which light energy is absorbed. Picosecond absorption measurements have suggested the existence of a transient intermediate produced before the batho intermediate which occurs in < 6 ps (ref. 28). This transient could represent the absorption of light by the state from which we are observing emission.

We can deduce from our data some information on the character of the excited state from which emission is observed. For example, the observation of vibronic structure in the 77 K emission spectrum suggests that the excited state involved in the emission has electron density delocalised in the polyene. This would increase the bond order of single bonds and decrease the bond order of double bonds. It has been suggested[2] that a lack of vibronic structure in the absorption spectrum can be attributed to the sterically hindered cyclohexene ring in the retinylidene chromophore Thus the C6–C7 single bond between the cyclohexene ring and the isoprenoid chain has a very broad ground-state potential. But if in the excited state the electron density is delocalised, the bond order of the C6–C7 single bond should increase and this in turn should narrow considerably the excited state potential surface for this torsional angle coordinate. Such an effect would reduce the conformational freedom of the cyclohexene ring relative to the isoprenoid chain and this should result in the vibronic structure observed in our emission spectrum. We believe it is significant that resonance Raman experiments on the batho intermediate (our unpublished results) which is stabilised from the excited state also indicate (from the frequencies of the C–CH$_3$, –C=N– and C=C vibrations) significant reduction in the C=C bond order and charge polarisation in this first stable product which results from a photon interacting with bacteriorhodopsin. Thus when the fluorescence and resonance Raman data are analysed together the excited state structure and electronic distribution seem to be a precursor and initiator of the stable batho photochemical product.

The blueshift we observed in the emission spectra when changing from room temperature to 77 K suggests that the chromophore is surrounded in the lipoprotein matrix by dipolar groups which have not relaxed fully at low temperature. In addition it is clear from the two beam experiments completed at 77 K that the batho form does not have the same excited state as this rhodopsin. Some theories of the photochemistry of rhodopsin have predicted that the excited states of rhodopsin and the batho intermediate are identical. Finally, the fact that no emission is observed for the batho form in the region of the spectrum where our apparatus is sensitive strongly suggests that the photochemical act which stores light energy in the 635-nm intermediate quenches radiative emission.

In conclusion, we feel that these observations of emission from a rhodopsin open new opportunities to understand the excited state ordering and structure of the retinylidene chromophore. Furthermore, these emission spectra will be important in understanding the primary photonic event which produces a red shift in the chromophores of all rhodopsins. Thus these data on the initial photochemically induced changes in the retinylidene chromophore should yield new insights into the conversion of light energy into chemical energy by rhodopsin, and should have an important role in the formulation of a mechanism of energy transduction by rhodopsin.

We thank Professor Walther Stoeckenius for bacteriorhodopsin and helpful discussions. We also thank Dr Richard Lozier for stimulating discussions; Professors A. Albrecht and H Mahr, Dr A. Kriebel, and M. Hirsch for obtaining the emission lifetime, and Professor R. Clayton for encouragement and obtaining the room temperature quantum efficiency A L. is an Alfred P. Sloan fellow; J.P.S. held an Eastman Kodak graduate fellowship; G.J.P. was supported by a graduate fellowship from the Ford Foundation. This work was supported by a grant from the National Institutes of Health.

Bicycle-pedal model for the first step in the vision process

Arieh Warshel*

Department of Chemical Physics, Weizmann Institute of Science, Rehovot, Israel, and MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

*Computer simulation of the molecular dynamics of retinal during its photoisomerisation inside a restrictive active site gives a detailed model for the sequence of events in the first step of the vision process. It is proposed that the prelumirhodopsin intermediate contains a strained all-*trans *retinal molecule produced directly and rapidly from the 11-cis, 12-s-*trans *conformation in rhodopsin by a bicycle-pedal isomerisation. The model reproduces the main experimental observations and explains how the protein makes the photoisomerisation path unique.*

IN the first step of the process of vision the rhodopsin molecule (a complex of 11-*cis* retinal and the protein opsin) absorbs a photon and undergoes a unique transition to the prelumirhodopsin intermediate[1]. (For a review of recent work see refs. 2 and 3.) Some of the most definite information about this reaction emerged from picosecond laser[4] and resonance Raman[5,6] experiments as well as from studies of artificial pigments[7-9]. The transition from rhodopsin to prelumirhodopsin takes less than 6 ps (6×10^{-12} s) and the retinal moiety in this intermediate is characterised by strong resonance Raman lines that do not appear in rhodopsin[5]. The interaction with opsin directs the pathways of photoisomerisation of quite different retinal isomers to the same all-*trans* final form[8]. In spite of the potential usefulness of this information there is no unique interpretation for any of these findings and the nature of the first step remains unresolved. It is reasonable to assume that the rhodopsin molecule uses the light energy for the photoisomerisation reaction of 11-*cis* retinal as fast as possible or else the excited state will be deactivated by radiation and radiationless processes. It is not clear, however, how the photoisomerisation can be accomplished in as large a molecule as retinal in such a short time[4,5] and how it can be done at all in a restricted active site[10]. Furthermore, there is no clue to the most intriguing mechanism by which the protein leads to only one final isomer from all the different initial complexes[8].

Recent theoretical developments[11-15] make it possible to analyse the available experimental information and to calculate reliably ground and excited state equilibrium geometries[12,13], absorption spectra[12,13] and resonance Raman spectra of retinal and related molecules (ref. 14 and my unpublished work with M. Karplus). It is also possible to simulate the dynamics of the photoisomerisation process and to monitor the conformational changes as a function of time[15]. In addition the interaction between the chromophore and hypothetical charges on the protein can also be evaluated[16]. The available theoretical approaches can be used to study various models for the visual excitation.

Here I propose a detailed model for the molecular events after the absorption of a photon by rhodopsin. The recently developed theoretical methods[12-16] are used to test the model against the principal experimental facts about the first step of the vision process and to stimulate the molecular dynamics of retinal during photoisomerisation. The following general assumptions are introduced in this model.

(1) The retinal is bound to a restrictive active site in which the cyclohexene ring, at one end of the molecule, is trapped in a hydrophobic cleft (this suggestion is supported by binding experiments[9] and by analogy to other enzymes) and the other end of the molecule (the "tail end") is bonded by a Schiff base bond (C=N) to a lysine residue of the protein. (2) No major conformational changes of the protein are involved in the first step (for discussion see refs 2 and 3). (3) The light energy must be used for isomerisation around the *cis* double bond, since this is the main energetic barrier of the visual process and it would be rather difficult to perform fast thermal isomerisation after the dissipation of the light energy. (4) In addition to these assumptions which are the working hypotheses of the model it is also assumed that the chromophore in rhodopsin is set initially to the 11-*cis*, 12-s-*trans* conformation (this assumption is supported by ref. 7 as well as by the work reported here) and that the Schiff base nitrogen is protonated[5,6]. It is further assumed that the protonated Schiff base bond is protected from hydrolysis by a negative group of the protein (a salt bridge) which increases the basicity of the Schiff base nitrogen.

Main features of the model

In the proposed model, described schematically in Figs 1 and 2, the chromophore is placed in the protein active site which is defined by assumptions (1) and (4). After absorption of light the *cis* bond is propagated to the tail end of the retinal chain by a 'bicycle-pedal'-like motion (see below). In this motion the molecule first changes its conformation by moving downhill on the potential surface of the excited singlet state and then crosses to the ground state once the C11–C12 torsional angle is approximately 90°. In the ground state the molecule becomes trapped in a strained all-*trans* (Fig. 2*d*) form, where the bond to the lysine residue forces the chain to bend and the salt bridge is stretched relative to its equilibrium distance in rhodopsin. This strained all-*trans* is the prelumirhodopsin intermediate in which the Schiff base nitrogen is less basic than in rhodopsin since its salt-bridge length is larger.

An important feature of the model is that all the isomerisation modes of different possible pigments can be executed by a concerted rotation about parallel pairs of double bonds ('bicycle-pedal motion'), as described in Fig. 2. In particular, the *cis* conformation can propagate from different double bonds to the terminal C=N bond. Thus, the protein makes the retinal change its conformation along a one-dimensional reaction path (essential for the large photon efficiency) simply by constraining the ends of the molecule so that it must move in a 'bicycle-pedal' motion rather than in all the possible modes of motion which are possible in solution[8].

Detailed examination of potential surface

The retinal intramolecular energy surface and its analytical derivatives were evaluated by the method already developed[12,13]. Since the barriers for rotation around double bonds are of special importance here, we recalibrated the potential parameters with particular emphasis on the reproduction of the

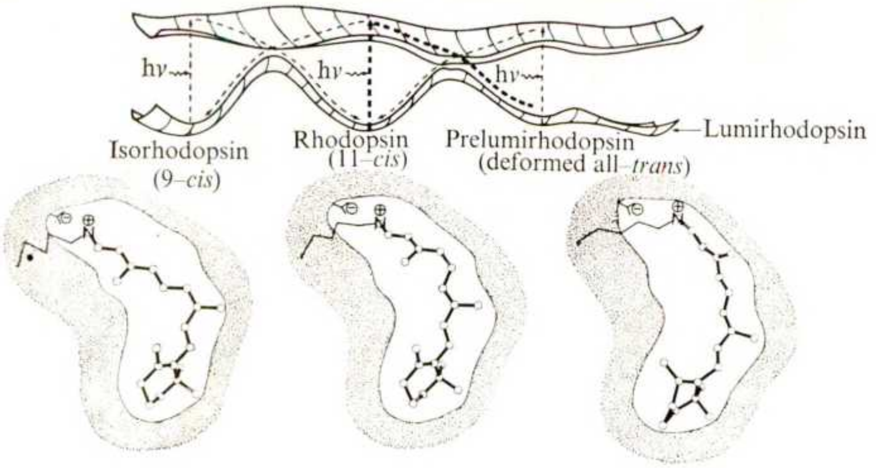

Fig. 1 A schematic description of the proposed model for the first step in the vision process. The figure presents the variation of the ground and excited state potential surfaces as a function of the adiabatic reaction coordinate and an effective perpendicular coordinate which represents all other coordinates. The change of the chromophore conformation in the enzyme active site are presented schematically below the surfaces. The thick broken line describes the primary visual process when the retinal chromophore of rhodopsin is excited by light to the first excited singlet, slides down, crosses to the ground state and becomes trapped in the prelumirhodopsin conformation. The thin broken line describes the mechanism of reversible transition between different intermediates.

potential surfaces of the ground and the first excited singlet and triplet states of ethylene. The calculation includes a configuration interaction treatment of all the single excitations and the low lying double excitations. The parameters for the Schiff base nitrogen were determined by an extensive fit to many independent properties of nitrogen-containing compounds (my unpublished work with A. Lappicesela)[12]. The σ electrons' charge distribution in the protonated Schiff base was determined by an all-valence electron approach[16]. In conventional semi-empirical quantum mechanical calculations the energy of the first excited singlet does not decrease smoothly as the C11–C12 double bond is twisted from 0° to 90° giving an activation barrier so that the singlet photoisomerisation becomes quite inefficient. We have found, however, that whenever the calculations include double configuration interaction treatment and Lowdin overlap correction[12,13] the energy decreases monotonically on twisting to 90° without any activation barrier.

The effect of the active site was included in the calculation by taking into account the main features of steric restriction and electrostatic interaction. The steric restriction on both the ring and the tail was simulated by forcing the ring carbons and the α carbon of the lysine residue to stay close to their positions in 11-*cis*, 12-s-*trans* retinal (the starting conformation). The electrostatic interaction with the enzyme was simulated by the recently developed "microscopic" dielectric model[16], using the atomic polarisability and average density of a typical protein (in this case lysozyme). It was found that while the effect of negative charge at various points along the chain can account for the spectral shifts between different pigments, its effect in modifying the surfaces is much smaller than that which could be expected in view of the sudden redistribution of the charges of the isolated chromophore on twisting of the C11–C12 bond to 90° (ref. 23). This effect is discussed below. Thus although the presence of external charges can reduce the spacing between the ground and excited states in the 90° region, the molecular dynamics calculation was performed with only a single negative charge near the N^{ε} of the lysine residue.

Simulation of photoisomerisation dynamics

If the transition between rhodopsin and prelumirhodopsin involves the proposed *cis–trans* photoisomerisation, then any simulation of this process must reproduce the fact that the transition is faster than 6 ps. The simulation should also account for the large quantum efficiency of the reaction and for the concept of a complete isomerisation in a restricted active site. Here the "semiclassical trajectory approach" is used to investigate surface crossing in photoisomerisation[15]. In this approach one evaluates classically the intramolecular motion (trajectory) on the excited state surface and then uses the calculated variation of the coordinates with time to evaluate quantum mechanically the transition probability to the ground state. At each point of large transition probability the trajectory is split into two parts—one crosses to the ground state and the second continues on the excited state surface. Each of these trajectories is weighted by the corresponding transition probability. Here we are dealing with a strong singlet–singlet coupling and the adiabatic representation[17,18] rather than the diabatic[15] one is used. The result of a typical trajectory is presented in Figs. 3 and 4, which show that the molecule can perform isomerisation inside a restrictive active site in about 2×10^{-13} s. This fast isomerisation is due to the small moment of inertia of the bicycle-pedal motion. Figures 3 and 4 also show that the molecules cross to the ground state with 30% probability during a single pass through the 90° region. Thus after about three passes (which corresponds to about 6×10^{-13} s) the probability of the molecule being in the ground state is almost 100%. The calculation clearly shows that a complete

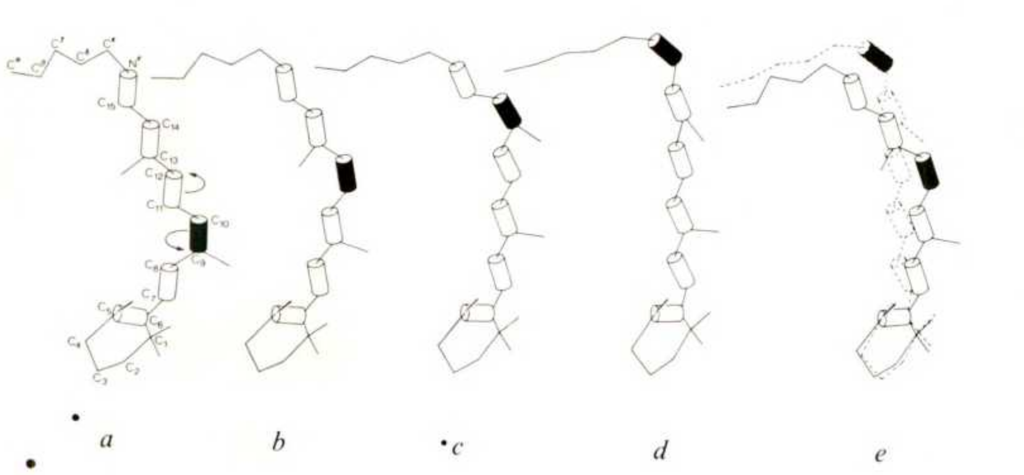

Fig. 2 Typical elements of the 'bicycle-pedal' mechanism. *a–d*, 9-*cis*, 11-*cis*, 13-*cis* and 15-*cis* isomers, respectively; *e*, the one-step concerted rotation about the 11–12 and 15–16 bonds which is the proposed motion in the visual excitation. Clearly with a system of parallel double bonds the *cis* bond can be transferred to any point without large shift into the atomic coordinates.

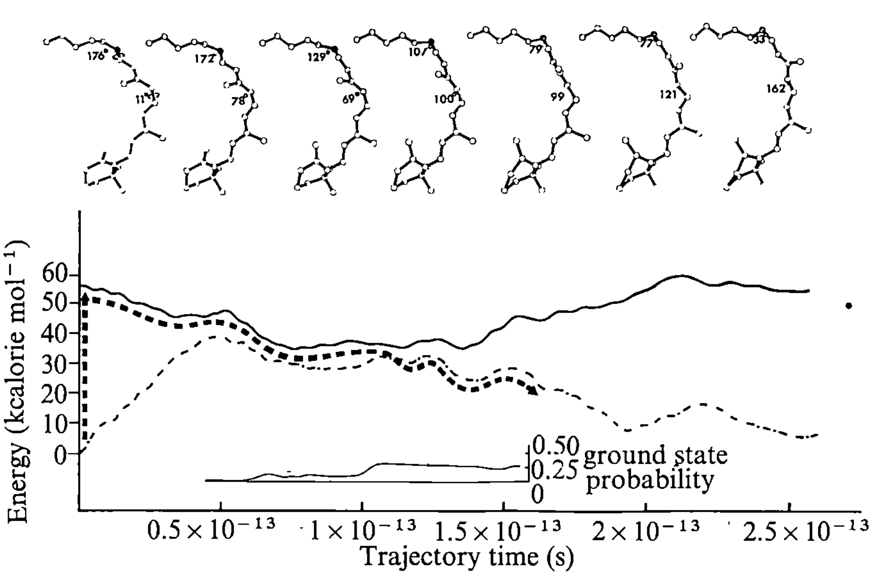

Fig. 3 Computer simulation of the first step in the vision process The figure presents a single trajectory which begins on the first excited singlet and crosses to the ground state at the point of maximum transition probability ($\varphi_{11-12} = 95°$) The potential energy of the ground and the first excited singlet are described by the broken and solid lines, respectively, as a function of the trajectory time while the conformational changes along the trajectory are presented above with the corresponding values of φ_{11-12} and φ_{15-16} The trajectory was obtained in the complete Cartesian space starting with the ground state equilibrium coordinates and zero kinetic energy The ring and the tail ends were constrained by assigning masses of 1,000 atomic units to the C1 and C5 ring carbons and to the Cα of the lysine residue. The humps on the potential surface along the trajectory are due to transfer of kinetic energy to potential energy in several bond-stretching, angle-bending and torsion vibrations The trajectory describes a dynamical rather than an equilibrium process and the dissipation of the excess torsional potential energy in the many normal modes (~200) of the system is not complete Thus in some energy fluctuations much of the kinetic energy is converted back to potential energy The probability of being at the ground state $a_0{}^2(\tau)$ is given as a function of the trajectory time as:

$$a_0(\tau) = \int_0^\tau \left[\langle \Psi_0 \mid \frac{\partial \Psi_1}{\partial t} \rangle a_1(t) \exp\left\{ -(i/\hbar) \int_0^t (E_1 - E_0) \mathrm{d}t' \right\} \right] \mathrm{d}t$$

where Ψ_0 and Ψ_1 are the ground and excited state electronic wave functions and E_0 and E_1 are the corresponding potential energies. In the actual evaluation of the *cis–trans* quantum yield the trajectory is split first at $\varphi_{11-12} = 82°$ where a trajectory with ~0 1 probability crosses to the *cis* ground state while the main trajectory continues in the excited state up to the point $\varphi_{11-12}=95°$ where it splits again with ~0 2 crossing to the ground state (this trajectory is shown in Fig 4), while another trajectory proceeds on the excited state with 0.7 probability This splitting procedure continues until the probability of the excited state trajectory is less than 0.1.

cis–trans photoisomerisation can be accomplished in less than 6 ps in contrast to previous suggestions[4]. Another important point is the fact that the calculated quantum efficiency is larger than 50%, indicating that the model system is almost as efficient as rhodopsin.

In contrast to the 'bicycle-pedal' motion the conventional photoisomerisation path involves a large rotation about the *cis* bond of either the ring[10] or the tail end. The resulting motion will be very slow due to the large moment of inertia and high probability for collision with the walls of the active site.

Resonance Raman and absorption spectra

The resonance Raman (RR) technique can provide unique information about the visual pigment as it measures the vibrational spectrum of the retinal inside the active sites of the protein Recent measurements have shown that prelumirhodopsin is characterised by lines in the 850–950 cm^{-1} region[5], which are not observed in rhodopsin or in Schiff base of retinal in solution. Our method for evaluation of vibronic transition intensities[14] can be used for direct calculation of the RR spectrum. This approach reproduces the main features of the RR spectra of Schiff bases of retinal in solution[14]. Model calculations have shown that the special lines of prelumirhodopsin can be reproduced if the chromophore is strained (my unpublished results with M. Karplus). The calculation of the RR spectrum of the present model of prelumirhodopsin (Fig. 2*d*) also reproduces two very strong lines at the 900 cm^{-1} region. These are due to a relatively large change in the geometry of the strained chromophore on electronic excitation.

Previous calculations of the dependence of the absorption maximum (λ_{max}) on external charges are reviewed in refs 2 and 3. In contrast to these works I include in my calculations the major effect of the protein polarisability[16]. This enables me to analyse properly the effect of external charges on λ_{max}. The degree of protonation was explicitly taken into account by calculating the σ charges of the retinal, the proton and the counter ion by an all-valence electron approach. I found that the redshift between rhodopsin (498 nm) and a protonated Schiff base of retinal in solutions (440–480 nm) can be accounted for by a calculated redshift of λ_{max} from 460 to 485 nm which is obtained when the salt bridge is placed in a more polar environment than the rest of the chromophore. An additional redshift of about 30 nm is obtained when the salt bridge is stretched from 2.5 to 4.5 Å. A further redshift of as much as 40 nm is obtained by another charged group properly placed near the chain, whereas a redshift of about 20 nm is obtained by ~ 10° twist about a double bond (obviously the shift can be increased by a larger twisting). Thus a significant part of the redshift between prelumirhodopsin (543 nm) and rhodopsin can be accounted for by a stretching of the salt bridge. The possibility, however, cannot be excluded that the redshift is due to the effect of double bonds twisting and/or changes in the distances between the chain and some negative or positive group. The inclusion of the polarisability reduces by about half the previously assumed effect of external charges[2,3]. Thus, it is likely that some part of the redshift between prelumirhodopsin and rhodopsin is due to twisting of double bonds. Essentially, Figs 1 and 3 show that a redshift of any magnitude can be obtained depending on the equilibrium value of φ_{11-12}, which is determined by the balance between the intramolecular potential of the chromophore and the constraint of the protein.

Another related fact, which introduces difficulties in other models[19], is the finding that the transition dipole is almost parallel in rhodopsin and the different bleaching intermediates[25]. This is clearly reproduced by my model which keeps all the double bonds parallel during the different stages of visual excitation.

Quantum efficiency and reversibility

An interesting and so far unresolved problem concerns the facts that prelumirhodopsin is a common intermediate for both rhodopsin and isorhodopsin I (9-*cis*)[5,10] and that the quantum efficiency of rhodopsin is about 0.7 while that of both isorhodopsin I and isorhodopsin II (9,13-*dicis*) is about 0.3 (ref. 8). This behaviour can also be studied by the semiclassical trajectory approach[15]. The calculated quantum efficiency for my rhodopsin model is about 0.6 A preliminary calculation starting with isorhodopsin I gave about 0 3 probability for

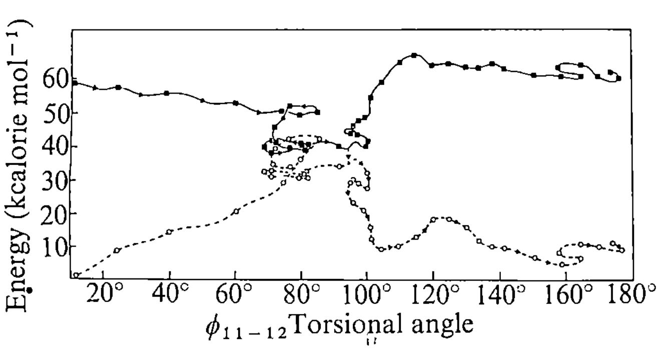

Fig. 4 The relationship between the potential surfaces and the φ_{11-12} torsional angle along the sample trajectory which is presented in Fig. 3 The trajectory time intervals (6×10^{-4} s) are represented by (○) and (■) for the ground and excited state, respectively. The actual potential surface taken by the trajectory is designated by (—›). The figure shows that the molecule forms some 'activated complex' and stays a relatively long time in the 90° region. The different values of the potential energy for similar values of φ_{11-12} are due to changes in other coordinates. Thus after the surface crossing φ_{11-12} varies slowly and the changes in the potential are due to changes in φ_{15-16} and φ_{9-10} as well as in various bond lengths and bond angles.

photoisomerisation in a 'bicycle-pedal' motion to rhodopsin (a similar part proceeds directly to prelumirhodopsin in a concerted rotation about the 9–10 and 15–16 bonds). With a second photon the rhodopsin proceeds with 0.7 probability to prelumirhodopsin. This suggestion can account for the fact that isorhodopsin I is about half as efficient as rhodopsin. The isomerisation of the isorhodopsin II (9,13-*dicis*) can be explained as described in Fig. 5: the molecule can move directly to prelumirhodopsin by a concerted bicycle-pedal rotation about the 9–10 and 13–14 bonds Alternatively the molecule can change its conformation to 11,13-*dicis* and then directly to all-*trans* by a second 'bicycle-pedal' motion of the two adjacent *cis* bonds.

The reversibility of photoisomerisation between prelumirhodopsin, rhodopsin and isorhodopsin (my unpublished results with M. Karplus) is accounted for by the fact that absorption of photons in one isomer populates its excited state, which can be relaxed to the ground states of the other isomers (Fig. 1).

Alternative explanations

Although other models of the visual excitation have been proposed[1,10,19-24], they did not provide unique isomerisation paths nor a detailed proposal for the conformation of prelumirhodopsin. Nevertheless, these models have some interesting features which are worth considering in terms of alternative explanations for the observations.

Recent calculations[23] have shown that the excited state charge distribution of the chromophore might change drastically on twisting of the C11–12 bond to 90°. A "short-lived electrical signal" mechanism was proposed as the primary event in the vision process. Such a mechanism seems to be unlikely as long as it implies a very short pulse rather than an irreversible change. The strong dependence of the excited state polarisation on the C11–12 torsional angle, however, presents the intriguing possibility that prelumirhodopsin has a twisted double bond where an external charge stabilises the excited singlet so that it becomes a ground state. If such a mechanism were operative along the 'bicycle-pedal' pathway it could account for many observations. My calculation, however, never reproduced this stabilisation effect, even with drastic changes of the semi-empirical parameters: that is, if the retinal charge distribution is not allowed to change in response to any external charge effect, then an optimally placed negative group could push the twisted excited state as much as 50 kcalorie mol^{-1} below the twisted ground state. When, however, a complete charge redistribution was allowed in my calculations, I was unable to push the excited state more than 5 kcalorie mol^{-1} below the ground state. This is because the presence of the negative charge near various points with a positive charge in the excited state of the isolated molecule induces positive charges in the ground state at the same points, which in turn makes the excited state charge less positive. I feel, however, that my model calculations cannot exclude completely the possibility that the chromophore in prelumirhodopsin is trapped in a twisted form by a strong interaction with some charged group of the protein.

Another suggestion is that the protonated Schiff base releases a proton in the primary event in the vision process[24]. The problem with this model is that the photoisomerisation must then be accomplished by thermal energy (this would cost about 25 kcalorie mol^{-1}) and the light energy will be wasted. Furthermore, the proton dissociation will cause a blueshift rather than a redshift in the absorption spectrum of prelumirhodopsin.

The possibility that the photoisomerisation is accomplished through the triplet state rather than the singlet state cannot be excluded completely. Recent experiments[26], however, support the singlet mechanism, and my study has shown that there is a significant barrier for isomerisation in the triplet. An estimate of the triplet–singlet coupling indicates that this coupling gives less efficient surface crossing than the non-adiabatic singlet–singlet coupling.

We cannot disregard completely the possibility that the prelumirhodopsin intermediate is not in a strained all-*trans* conformation but in other conformations along the reaction path between 9-*cis* and 11-*cis*. Such a ground state conformation which requires a large twist about the 10–11 single bond as well as about the 9–10 and 11–12 double bonds might be possible if rhodopsin actually binds retinal in the 11-*cis*, 12-s-*cis*-form rather than 11-*cis*, 12-s-*trans* form. The photon efficiency of this system, however, should be less than 0.3 since the sum of the probabilities of isomerisation to 9-*cis* and of return to 11-*cis* is larger than 0.7.

It is clearly possible that the chromophore in prelumirhodopsin is in a much more twisted form than the one obtained by my potential surfaces. That is, the protein can provide such an external constraint which will stop the isomerisation in an earlier stage where φ_{11-12} and other torsional angles are strongly twisted. Obviously in this case the strain energy at prelumirhodopsin will be higher than that implied by the present calculation.

Implications of the model

The model presented here accounts for the main observations concerning the first step in the vision process. It is consistent with the ultra-fast transition from rhodopsin to prelumirhodopsin; the changes in the RR and absorption spectra during the transition, and the conservation of the direction of the transition moment. The model explains the uniqueness of the photoisomerisation process and its high quantum efficiency as well as the reversibility of transitions between the different pigments. The model is also consistent with present understanding of steric effects and charge stabilisation: that is, a

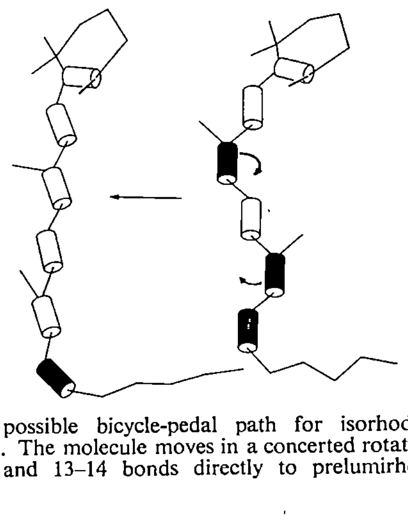

Fig. 5 A possible bicycle-pedal path for isorhodopsin II (9, 13 *dicis*). The molecule moves in a concerted rotation about the 9–10 and 13–14 bonds directly to prelumirhodopsin

steric strain by the protein is not effective if it can be relaxed by small displacements of the corresponding atoms. On the other hand, the steric effect may be important when the molecule is trapped in a twisted form by a constraint which can be relaxed only by large conformational changes. The charge effect (which was proposed as a very efficient way of controlling enzymatic reactions[16]) is used here with a salt bridge to the protonated Schiff base, whereas a fine tuning of the system can be obtained by other charged residues optimally placed along the chain.

It now seems that the first step of the vision process can be described as follows. Light absorption by rhodopsin populates the first excited electronic singlet state of the 11-*cis* retinal chromophore (which is bound at both ends as proposed here). The excited retinal slides in a very fast 'bicycle-pedal' motion to the 90° twisted singlet and then crosses to the ground electronic state while continuing to slide towards the *trans* form (Fig. 1). The protein defines a unique isomerisation valley for the conjugated chain by restricting the motion of both the ring end and the tail end and by some charge stabilisation. The use of the protonated Schiff base system with a proper charge stabilisation guarantees efficient singlet–singlet crossing and allows the system to perform very efficient isomerisation before other deactivation processes can take place After the surface crossing step, the chromophore is trapped in a high energy strained form (prelumirhodopsin) and the basicity of the Schiff base nitrogen is reduced as a result of the increase in distance between the negative residue and the N^{ϵ} relative to that in rhodopsin. In the next stage of the reaction (lumirhodopsin) λ_{max} is blueshifted by $\sim$45 nm relative to prelumirhodopsin. This shift might indicate changes in the polar environment of the Schiff base bond and/or other parts of the chromophore, as well as a decrease in the torsional deformation of some double bonds of the chromophore. Such changes are possible (when the temperature is increased and prelumirhodopsin is changed to lumirhodopsin) as a result of a partial release of the chromophore strain which involves some small conformational changes of the protein The release of strain and the new balance of the electrostatic interactions lead to more significant conformational changes of the protein during the steps lumirhodopsin to meta I to meta II. The spectral changes in the meta I to meta II step[1] indicate that the Schiff base proton is dissociated after further decrease in the basicity of the Schiff base nitrogen. In contrast to the situation in rhodopsin the non-protonated Schiff base in meta II can undergo hydrolysis by water. The protein conformational changes serve to convert the light signal into an electrical membrane current, somewhere along the pathway between prelumirhodopsin and meta II. These stages, however, do not involve further isomerisation of the chromophore.

It seems clear that in designing this photoconverter machine the two boundary conditions, which in turn establish the 'bicycle-pedal' mechanism, are important. In this way the system is forced to move in what is effectively one dimension along the complex energy surface as the *cis* bond is transferred backwards and forwards. Thus it seems that a promising way to simulate the surface crossing in rhodopsin might be achieved by a chemical approach of building a model compound with a Schiff base bridge between the ring to the end of the chain.

Yoshizawa and Wald have proposed[27] that the retinal molecule in this intermediate is in a strained all-*trans* conformation. Although the details of the transition between rhodopsin to prelumirhodopsin and the binding of the cyclohexene ring[1] were not clear at that stage, some features are common to both models.

I thank M. Levitt for encouragement and critical discussion and M. Karplus and B. Honig for stimulating discussions in the early stages of this work. This work was supported in part by the United States–Israel Binational Science Foundation and by the European Molecular Biology Organization.

The nucleus of Centaurus A

A. C. Fabian, D. Maccagni*, M. J. Rees & W. R. Stoeger

Institute of Astronomy, Madingley Road, Cambridge, CB3 0HA, UK

The nucleus of Centaurus A contains a very compact radio component, and has recently been discovered to be a variable X-ray source. We argue that these phenomena arise from accretion on to a massive black hole. Possible implications for galactic nuclei in general are briefly discussed.

CENTAURUS A, at a distance of $\sim$5 Mpc, is the closest radio galaxy. Its total radio power is now only $\sim 10^{42}$ erg s^{-1}. The energy content of the very extended radio lobes is, however, $\sim 10^{60}$ erg, and this suggests that Cen A may once have been a powerful radio source of the same type as, for instance, Cygnus A. Recent observations of apparent radio and X-ray variability provide evidence for continuing activity in the nucleus of Cen A. Even though this activity involves a much smaller power output than occurs in QSOs and strong radio sources, it may suggest clues to the nature of active galactic nuclei in general. We discuss here the implications of the new data (particularly the X-ray variability), and argue that they perhaps indicate the presence of a massive ($\gtrsim 10^{7} M_{\odot}$) black hole in Cen A.

Kellermann[1] has detected a central radio component with luminosity $\sim 4 \times 10^{40}$ erg s^{-1} whose spectrum cuts off below $\sim$30 GHz. If the cutoff results from synchrotron self absorption, the size of this component would be only $\sim 10^{16}$ cm. There is some evidence[1,2] for variability on time scales as short as a day.

Cen A is also an X-ray source. Davison *et al.*[3] found that the X-ray intensity had varied over a two-year interval, and therefore proposed that it was associated with a very compact nuclear source. This variability has been confirmed by independent measurements[4-6]; indeed Winkler and White[4] reported X-ray variability of a factor 1.8 ± 0.2 within only 6 d. The spectrum is hard, and there is evidence for variability at photon energies up to $\gtrsim 100$ keV (ref. 7). The X-ray power at <100 keV is $\sim 5 \times 10^{43}$ erg s^{-1}. Hall *et al.*[7] report a γ-ray continuum extending up to ~ 5 MeV, with possible lines at 1.6 MeV and 4.5 MeV; and very high energy ($\gtrsim 300$ GeV) γ rays have been claimed[8].

Previous discussions of the nature of the X-ray source in Cen A have concentrated on non-thermal models[9-11], and do not specify the source of the necessary relativistic electrons. The idea that massive black holes may lurk in galactic nuclei[12,13] is appealing for several reasons. A black hole seems the likely endpoint for the evolution of a supermassive star or dense star cluster (these being two alternative models for an active galactic nucleus) and accretion on to a black hole can itself account for various phenomena associated with galactic nuclei. If it (or its progenitor) had generated the entire energy content of the extended radio source, the black hole in Cen A would be $\gtrsim 10^7 M_\odot$. In what follows we consider a hole of mass 10^7 M_7 solar masses (and Schwarzschild radius $r_S \simeq 3 \times 10^{12}$ M_7 cm).

Accretion on to massive black holes

If the X rays are thermal bremsstrahlung, then the hard spectrum implies that the temperature is $T \simeq 10^9$ K (in reality, of course, one might expect different parts of the source to span a range of temperature). If the emission comes from gas occupying a sphere of radius r around the black hole, with a volume 'filling factor' f, then the approximate mean particle density n must be

$$n \simeq 10^{14}\left(\frac{r}{r_S}\right)^{-3/2} f^{-1/2} M_7^{3/2}\ \mathrm{cm}^{-3} \tag{1}$$

The ratio of the bremsstrahlung cooling time

$$t_{\mathrm{br}} \simeq 3 \times 10^{11} T^{1/2} n^{-1}\ \mathrm{s}$$

to the free fall time scale

$$t_{\mathrm{ff}} \simeq 10^2 M_7 \left(\frac{r}{r_S}\right)^{3/2}\ \mathrm{s}$$

is then

$$t_{\mathrm{br}}/t_{\mathrm{ff}} \simeq f^{1/2} M_7^{1/2} \left(\frac{T}{10^9\ \mathrm{K}}\right)^{1/2} \tag{2}$$

For the parameters appropriate to Cen A, this ratio never greatly exceeds unity (and it can be made $\ll 1$ by taking a small filling factor); so the efficiencies are adequate provided that the gas can be heated to $T \geqslant 10^9$ K.

If ε denotes the efficiency of the accretion process in converting rest mass into X rays, then the required mass inflow rate is $\sim 10^{-3}\ \varepsilon^{-1}\ M_\odot\ \mathrm{yr}^{-1}$. The corresponding particle density, at distance r from the hole, would be

$$n(r) \simeq 3 \times 10^{11} \varepsilon^{-1} f^{-1} \left(\frac{r}{r_S}\right)^{-3/2} M_7^{-2} \left(\frac{v_r}{v_{\mathrm{ff}}}\right)^{-1}\ \mathrm{cm}^{-3} \tag{3}$$

If transverse motions or pressure gradients slow down the inward velocity, so that the radial velocity v_r becomes $\ll v_{\mathrm{ff}}$, note that n is correspondingly higher for a given mass accretion rate. Equations (1) and (3) cannot be compared directly, since v_r, f and T are probably all functions of radial distance r. They do indicate however that even radially infalling material may produce the observed X rays if $\varepsilon \sim 10^{-3}$, $f \sim 10^{-1}$ and $M_7 \sim 1$.

When the specific angular momentum of the captured material greatly exceeds $a_{\mathrm{crit}} = 2cr_S$, we expect the formation of a significant accretion disk extending well beyond $6r_S$; and it is well known that in this situation a high radiative efficiency $\varepsilon \simeq 0.1$ is almost guaranteed. The 'standard' model[14], however, then predicts disk temperatures of only $T \lesssim 10^5$ K for $M_7 \gtrsim 1$ (no X rays at all). This is because the required luminosity is far below the 'critical' luminosity $\sim 1.3 \times 10^{45} M_7$ erg s^{-1} for such a massive black hole. The inner, radiation pressure supported, region of the disk is therefore thin. The factors f and v_r/v_{ff} in equation (3) are then both very small, and n becomes so high that bremsstrahlung is efficient even at quite low temperatures.

The other well studied type of accretion is that where the inflow is radial (zero angular momentum) and laminar. We see from equation (2) that $t_{\mathrm{br}}/t_{\mathrm{ff}}$ increases with T. The problem here is therefore that if this factor is to be $\lesssim 1$ near the hole, it would have been $\ll 1$ at larger radii. The gas would therefore have remained cool, and the radiative output derived from '$p\mathrm{d}V$ work' would be low[15]. (We avoid introducing the usual concept of 'accretion radius' in this context, because, (1) at large distances the gravitational field of the whole galactic nucleus dominates that of the hole itself, and (2) most of the gas may in fact be produced at a radius where the escape velocity is supersonic.)

Quasi-spherical accretion

Of course there are many ways in which the above models could be modified to account for reasonably efficient production of hard X rays. For instance, realistic disks may involve hot coronae, magnetic flares, and so on. Alternatively, as emphasised by Mészáros[16], continual dissipative heating from turbulence or magnetic field reconnection could raise the efficiency and temperature in the radial inflow picture; but, where cooling is efficient, this model is still constrained by the requirement that

$$kT(r) \lesssim 10^{12} \left(\frac{r}{r_S}\right)^{-1} \frac{t_{\mathrm{br}}}{t_{\mathrm{ff}}}$$

We wish to point out, however, that the X-ray data are most readily explained by an 'intermediate' model where the infalling material has a small but significant specific angular momentum a in the range (say) $1\text{–}30 \times a_{\mathrm{crit}}$. A typical element of gas must then lose its excess angular momentum before it can fall into the hole. (This type of process can in principle yield higher efficiencies than disk accretion. Consider, for instance, two identical (and very small) gas clouds dropping towards a Schwarzschild black hole in orbits having equal opposite angular momentum. If these clouds collided at the point r_{min} when their orbits pass closest to the hole they would come momentarily to rest. If the energy of impact were radiated away, the efficiency would be $1-[1-(r_S/r)]^{1/2}$. For clouds with the critical angular momentum, a_{crit}, the corresponding volume of r_{min} is $2r_S$. This yields an efficiency of 29% (neglecting a correction for the fraction of radiation that would itself be swallowed).)

We can envisage two possibilities: firstly, the accreted material may all have the same sense of rotation. In this case a disk will initially form at a radius $\sim(\langle a \rangle/a_{\mathrm{crit}})^2 r_S$. If the flow continues steadily for a long time, then viscous effects in the disk may cause its rim to grow outwards, but (except in the plane of the disk) inflowing gas would still join the disk after passing through a shock at radius $\sim(\langle a \rangle/a_{\mathrm{crit}})^2 r_S$. Secondly, even if there were no steady systematic rotation, a unit mass of infalling gas might have some angular momentum $\sim a$ arising from small random transverse velocities far from the hole. If $a > a_{\mathrm{crit}}$, this material could not be swallowed until it had lost its angular momentum by colliding with counter-rotating fluid elements near the hole.

In either of the above cases, infalling material will be shocked at a radius $r_{\rm shock} \simeq (\langle a \rangle / a_{\rm crit})^2 r_{\rm s}$, the temperatures attained being $\sim 10^{12}\,(r_{\rm s}/r_{\rm shock})$ K. Thus if $r_{\rm shock} \lesssim 10^3 r_{\rm s}$ the temperatures would be high enough to produce a bremsstrahlung spectrum extending up to photon energies of at least 100 keV. Moreover if $t_{\rm br} \lesssim t_{\rm ff}$ the shocked gas will have time to cool down before being swallowed, thus ensuring reasonable efficiency. The 'impulsive' form of heating from shocks can in this case result in much higher temperatures than from a continual dissipative release of energy.

Most of our discussion is independent of which of these two alternatives applies, and is therefore insensitive to the actual origin of the accreted gas. One interesting possibility is that the gas results from tidal breakup of stars passing close to the black hole[13]. This mechanism can plausibly provide an adequate supply of material; moreover this material would necessarily have angular momentum corresponding to orbits near the 'tidal radius' of the black hole—$\lesssim 10 a_{\rm crit}$ for appropriate parameters[13].

The variability and spectrum of the X rays would, in this scheme, be determined by the details of the inflow, which in turn depends on the origin of the accreted gas. If $M_7 \simeq 1$–10 there is, however, no problem with accounting for variability on any time scale down to hours.

For the spectrum to extend into the MeV band, shocks would need to occur where $r/r_{\rm s} \lesssim 100$. Note that there would then be additional cooling due to electron bremsstrahlung, pair production and 'Comptonisation'. These processes would reduce the cooling time, thus improving the efficiency and strengthening the need for impulsive rather than dissipative heating.

According to Hall *et al.*[7], the spectrum extends up to ~ 5 MeV, and this permits us to set a tentative rough lower limit of $r \gtrsim 10^{15}$ cm to the source dimensions. This limit (which is somewhat geometry dependent) corresponds to the requirement that the 'column density' of hard X-ray photons in the source should not be so high that the γ rays produce e^-–e^+ pairs before escaping[17].

The radio source in the nucleus

The (probably variable) radio component, whose dimensions are also 10^{15}–10^{16} cm, may well be associated with the region that emits the variable X rays. Indeed, the same shock waves which heat the infalling gas may also generate the relativistic electrons. This possibility cannot be explored quantitatively without estimating the magnetic field structure in the gas, or discussing acceleration mechanisms. One can, however, exploit an analogy with supernova remnants such as Cas A, where shock waves involving velocities somewhat lower than we envisage have certainly converted $\gtrsim 1\%$ of the available energy into relativistic electrons. The very high energy γ rays reported by Grindlay *et al.*[8] are presumably somehow associated with the non-thermal radio source.

Radio variability on a time scale of months or years is a well known occurrence in many QSOs, and in the nuclei of some strong radio galaxies. It is commonly interpreted as a succession of 'outbursts', which each produce an expanding cloud of relativistic plasma. VLBI measurements provide evidence for changing structure in these components, and it has been widely argued[18,19] that the outbursts represent successive supernova-style events each releasing $\sim 10^{53}$ erg· the inferred energy per outburst, the event rate (~ 1 yr^{-1}) and the mean luminosity of the galactic nucleus are all compatible with this view. Kellermann[1] emphasises that the nucleus of Cen A resembles a scaled-down version of these other variable sources. The event rate is, however, higher and the mean power output much lower. It seems implausible that supernovae are going off at a rate of 1 d^{-1} in Cen A, which is an order of magnitude less luminous than QSOs. Instead, it seems that the radio outbursts in active nuclei involve flares whose energy is correlated with the mean luminosity (as expected in an accretion picture), rather than supporting a 'building block' model where the energy per outburst is standardised. Moreover, we have shown that the massive black-hole hypothesis accounts naturally for the emission of variable thermal X rays with a hard spectrum. (That 3C279 produced optical flares involving $\gtrsim 10^{54}$ erg (ref. 20) raises problems for the multiple-supernova model in the opposite direction.)

If the nucleus of Cen A involves supernova-type events in a dense star cluster massive and long lived enough to have powered the extended radio source, then the present activity should be spread over a ~ 1 pc region. This corresponds to an angle $\sim 0.04''$—large by the standards of VLBI techniques. Thus if the radio source, when it has been observed for a longer interval, fails to display any 'jitter', this would support the kind of model proposed here involving a massive black hole. It would not, of course, preclude the possibility that a dense star cluster is indirectly involved, as envisaged by Hills[13].

Discussion

Accretion of material with low, but not negligible, specific angular momentum by a massive black hole can be an efficient means of producing hard X rays. Mészáros[16] has emphasised that dissipative heating may greatly enhance the efficiency when $a < a_{\rm crit}$, and we find that shocks involving velocity discontinuities of $\gtrsim 0.1c$ can occur in the intermediate case of $a_{\rm crit} < a < 30 a_{\rm crit}$. Radiation from behind such shocks can produce a hard spectrum extending up to $\gtrsim 1$ MeV. This mechanism can account for the observed X-ray emission from the nucleus of Cen A. The variability in the X-ray source may arise from changes in the mass flow rate, or amount and distribution of angular momentum in the infalling gas. (An analogous model may be relevant to Cygnus X-1 (refs 21–23).) 'Standard' accretion models[14,15] fail to account for hard X-ray emission from massive black holes.

A similar model may also apply to the nucleus of 3C390.3, which is possibly a variable X-ray source[24], and such objects as NGC4151 and 3C273. The strong X-ray absorption observed[25] in these last two suggest again that the nucleus is responsible. An alternative scheme involving multiple stellar mass 'events' in a dense star cluster might be tested by searching for jitter with VLBI techniques. It is also possible in this case that the X-ray absorption might change if a substantial fraction of the absorbing material lies in the star cluster. If the analogy between Cen A and more powerful galactic nuclei is genuine, the implications for theories of extragalactic violent activity in general would be basic and fundamental.

Source of terrestrial non-thermal radiation

Dyfrig Jones

Space Science Department, European Space Research and Technology Centre, Noordwijk, The Netherlands

Observations from satellites have revealed the existence of continuum radiation from just beyond the plasmapause. I propose here that this is generated by Cerenkov radiation coupling to the O mode of radiation, which can propagate in low density plasmas. The observations are interpreted on the basis of this theory.

RECENT observations by spacecraft of radio noise at distances beyond about six Earth radii (R_E) from the Earth indicate the presence of non-thermal continuum radiation (ref. 1, and D. A. Gurnett, unpublished) in the frequency range 500 Hz–100 kHz. Direction finding measurements on the Imp 6 spacecraft show that the radiation is generated in the outer radiation zone immediately beyond the plasmapause boundary[1]. The source region extends from 0400 to 1400 (LT) and covers a broad latitude range, which includes the geomagnetic equator (D. A. Gurnett, unpublished); a separate source exists on the morning side of the magnetosheath.

The radiation has a sharp lower frequency cut-off near to the local electron plasma frequency, f_p, which is proportional to the square root of the electron density in the vicinity of the spacecraft; f_p ranges from 500 Hz in the distant magnetotail to >100 kHz near the plasmapause. No distinct high frequency cut-off is observable and the intensity decreases as the frequency increases; > 100 kHz the radiation disappears below the cosmic noise level. The continuum seems to consist of two components, one which fills the whole magnetosphere and magnetotail and which is permanently trapped between the plasmasphere and magnetosheath, and another component which can penetrate the magnetosheath to propagate freely into the solar wind[2,3].

A spectrogram showing the low frequency cut-off of the radiation when Imp 6 was situated at ~8R_E and 0545 (LT) is seen in Fig. 1, where the picture intensity is proportional to the amplitude of the noise. The signals from the electric and magnetic antennae are shown alternately; the magnetic signal appears weaker because the experiment sensitivity to this component is less.

The radiation is seen to have two distinct cut-offs, one at frequency $f_1 \simeq 5.3$ kHz and the other at $f_2 \simeq 6.35$ kHz. In the range between f_1 and f_2 the noise varies periodically as the spacecraft rotates, the nulls in the observed electric component occurring when the electric field vector of the radiation is perpendicular to the dipole antenna used for reception. It is stated that this electric field is polarised predominantly parallel to the geomagnetic field[1]. At frequencies $>f_2$, bands of noise are apparent at ~7.7 kHz, 8.6 kHz and 9.4 kHz. These bands are not always observed but seem to appear irregularly when the spacecraft is close to the plasmapause. Since they are observed on both electric and magnetic channels they are apparently electromagnetic in character.

Mechanisms which have been proposed as a source of the continuum radiation are gyrosynchroton radiation[3] and electrostatic instabilities at half harmonics of the electron gyrofrequency[1], that is at $(n+\frac{1}{2})f_g$ where n is an integer and f_g is the gyrofrequency (which is proportional to the magnetic field strength). There is recent evidence (D A. Gurnett, unpublished) that the radiation is dependent on the flux of particles of energy <30 keV and this tends to eliminate the gyrosynchroton mechanism which requires particles of much higher energy, ~1 MeV. The second mechanism proposed—electrostatic instabilities—requires that the energy be transferred from electrostatic waves to electromagnetic waves and it is suggested that this can occur if the medium is inhomogeneous.

I here propose that the observed radiation is produced originally by the Cerenkov mechanism as electromagnetic waves in a mode that cannot normally propagate over large distances in the magnetosphere. Close to the source region, however, these waves may become coupled to electromagnetic waves in another mode which can propagate over large distances.

Theory

Cerenkov radiation is produced when particles are moving through a medium with velocities greater than the phase velocity of the radiation in the same direction. Since particle velocities cannot exceed the velocity, c, of electromagnetic radiation in free space, the Cerenkov criterion requires that the wave refractive index be greater than unity; the lower the speed of the particle, the larger the refractive index required.

Figure 2 illustrates the variation of the square of the refractive index (n^2) with X, when $Y < 1$ and collisions and temperature effects are neglected[4]; the parameters X and Y are as normally defined in magnetoionic theory[5]

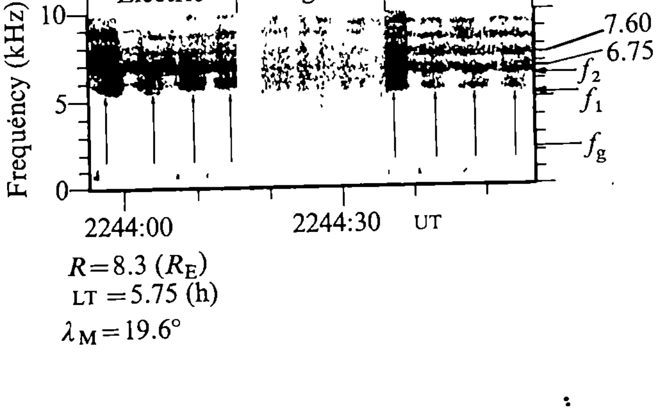
$$X = f_p{}^2/f^2; \qquad Y = f_g/f,$$

where f is the wave frequency and f_p, f_g are the plasma frequency and gyrofrequency respectively. The condition $Y < 1$ requires that $f > f_g$; this condition and the assumption that collisions can be neglected are satisfied for wave frequencies >5 kHz at radial distances of $\geq 6R_E$.

It is apparent from Fig. 2 that three modes of propagation are possible for the range of X shown. The mode whose refractive index goes to zero at (the mode with a cut-off at) $X = 1 - Y$ is the first extraordinary mode—the X mode. The mode with a cut-off at $X = 1$ is the ordinary (O) mode, and the mode having a cut-off at $X = 1 + Y$ is the second extraordinary mode, usually termed the Z mode. The shaded regions indicate where the curves of n^2 must lie as the angle θ between the wave normal direction and the magnetic field direction is varied; the full lines labelled a, b and c show the curves corresponding to some wave-normal angle θ intermediate to 0 and $\pi/2$.

It is important to note that as $\theta \rightarrow 0$, when the wave normal and magnetic field directions tend to be parallel (or antiparallel),

Fig. 1 v.l f Spectrogram obtained on Imp 6 (from ref. 1). Arrows indicate electric antenna parallel to geomagnetic field.



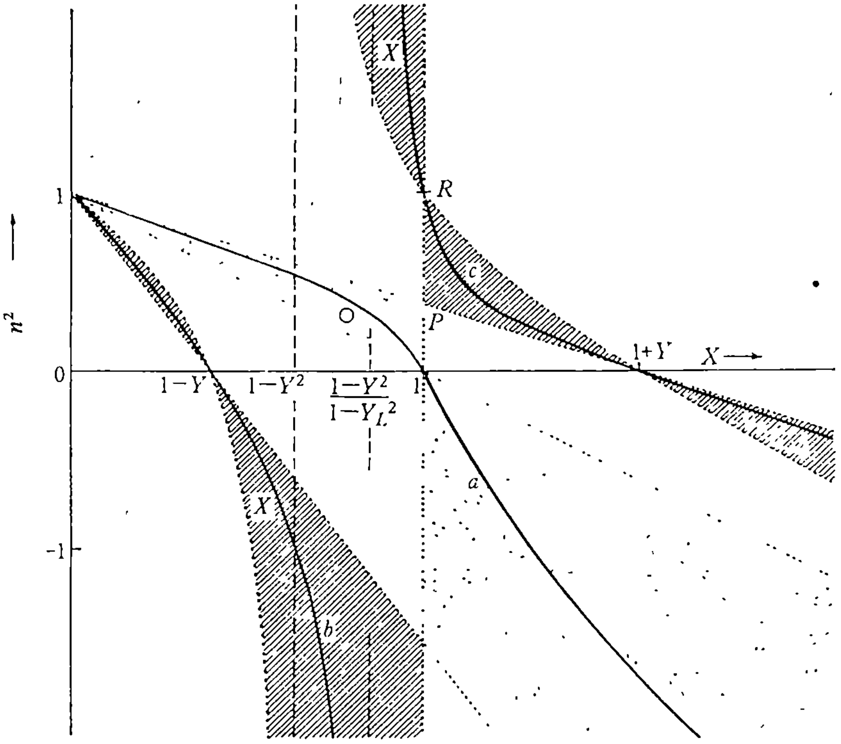


Fig. 2 Variation of (refractive index)^2 with X when $Y<1$ (after Budden[4]). Electron collisions are neglected.

the curves a and c approach the point P at $X = 1$. The refractive index for the Z mode increases rapidly $< X = 1$ and $\rightarrow\infty$ at $X = (1-Y^2)/(1-Y_L^2)$ where $Y_L = Y\cos\theta$. As $\theta \rightarrow 0$, $Y_L \rightarrow Y$ and the infinity in $n \rightarrow X = 1$; as $\theta \rightarrow \pi/2$, $Y_L \rightarrow 0$ and the infinity $\rightarrow X = 1-Y^2$. This infinity is termed the upper hybrid resonance (UHR).

The Cerenkov criterion can be satisfied only in the region $1-Y^2<X<1$ since it is only there that $n>1$. Observations on rockets and satellites in the ionosphere and magnetosphere[6-16] show that under certain conditions, enhanced radiation, which has been called UHR noise, does exist in this frequency range extending from the plasma frequency $f = f_p$ ($X = 1$), to the UHR frequency $f = (f_p^2+f_g^2)^{1/2}$. Calculations show that Cerenkov radiation from typical magnetospheric energy spectra is adequate to provide the power observed in UHR noise[17]. With reference to Fig. 2, it is clear that UHR noise cannot escape directly to regions of lower plasma density (smaller X) since the radiation is absorbed at the UHR. If, however, the Z waves propagate first into regions of increasing plasma density and reach the level $X = 1$ where the wave frequency becomes equal to the plasma frequency, then it is possible in certain conditions for the energy to be transferred or 'coupled' from the Z mode to the O mode. The O-mode energy is then free to propagate to lower values of X as is apparent from curve a in Fig. 2.

The theory of coupling[4] yields a coupling parameter ψ given by the expression

$$\psi = -\frac{iY_T^2Y_L}{4}\frac{X^1+iZ^1}{(1-X-iZ)^2Y_L^2+(Y_T^4/4)} \qquad (1)$$

where $Y_T = Y\sin\theta$ and Z is the ratio of collision frequency to wave frequency and must not be confused with the Z mode. The parameters X^1 and Z^1 are the spatial gradients of X and Z respectively It is seen from equation (1) that ψ can become large if simultaneously $X\rightarrow 1$ and $Z\rightarrow(1/2)|Y_T^2/Y_L|$. These are the conditions for 'critical coupling'. In the magnetosphere beyond a few thousand kilometres altitude, the value of Z computed on the basis of Coulomb collisions is small and thus critical coupling is achieved if $Y_L \gg Y_T$ at $X = 1$. Therefore, one can expect energy transfer from the X mode to the O mode near $X = 1$ if the wave normal direction is close to the magnetic field line direction; in this condition curves a and c in Fig. 2 approach one another at point P.

Further theory

To understand in more detail the emission process and the consequent wave propagation and coupling, it is necessary to consider the refractive index surfaces (n surfaces). An n surface is a surface on which lies the tip of a vector whose direction is that of the wave normal and whose magnitude is proportional to the phase refractive index for that direction. The n surfaces for the Z mode are illustrated in Fig. 3a. For a given value of Y, a family of n surfaces may be drawn corresponding to different values of X. The surfaces are in fact surfaces of revolution about the geomagnetic field $\mathbf{B}_0$

To determine graphically the wave normal angle at which Cerenkov radiation is produced by a particle with velocity $c\beta$ along the magnetic field, $\beta<1$, a line may be drawn normal to $\mathbf{B}_0$ at a distance $1/\beta$ from the origin. Where this line intersects an n surface—for example at M in Fig. 3a—the Cerenkov condition is satisfied; the radiation produced at the level corresponding to $X = 0.9$ will then have its wave normal along **OM**. Note that for $X<1$ the shape of the n surfaces is such that particles of all energies (all values of β) will produce waves all of which have nearly the same wave normal direction. In practice, temperature effects limit n to finite values, so that the lower energy particles do not contribute to the power radiated. After the waves are produced, propagation into regions of lower or higher X may be followed by using Poeverlein's construction. This is based on Snell's law, which requires that the tangential components n be equal above and below an isoionic plane (plane of constant X) through which the wave travels[7]. In Fig. 3a consider the isoionic plane AA' which has been selected so that its normal passes through points M and P; the significance of this will appear later. The original wave normal direction is along **OM** but the group velocity of the wave is in the direction perpendicular to the n surface at M (see Budden[4]) as indicated by the small arrow; this is the ray direction. If the energy propagates into regions of increasing electron density (increasing X) the locus of the tip of the wave normal moves from n surface to n surface along the line MN. The ray path resulting from the condition that the ray direction should

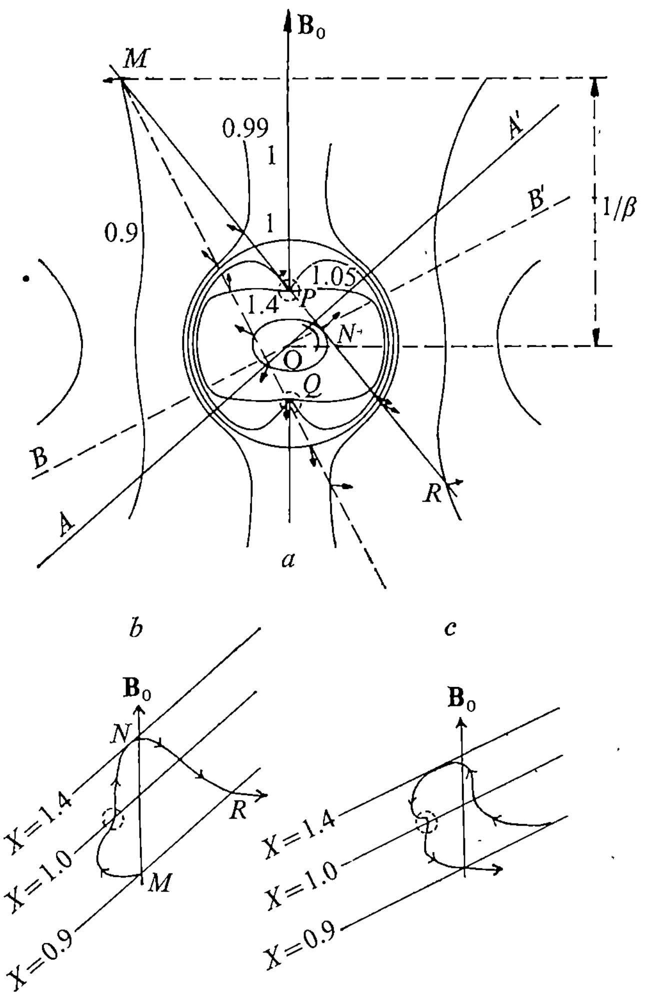

Fig. 3 *a*, Refractive index surfaces for the *X*-wave when $Y<1$. Figures on the curves are values of *X*. *b*, Ray path with isoionic contours *AA'*. *c*, Ray path with isoionic contours *BB'* The dotted circles indicate the regions of coupling.

always be normal to the *n* surfaces at the tip of the wave normal is shown in Fig. 3*b*. At point *N* the wave is reflected, its wave normal following the line **NR** in Fig. 3*a* and its ray following *NR* in Fig. 3*b*.

It is evident from Fig. 3*a* that when the waves pass through the region corresponding to $X = 1$, the wave normal becomes aligned with $\mathbf{B}_0$ and the two conditions for critical coupling are satisfied. Energy can be transferred at this point from the *Z* wave to the *O* wave whose *n* surface at this level also passes through point *P* as can be deduced from Fig. 2 (see also Budden[4]). The *O* wave so produced cannot propagate into regions of higher *X* (see Fig. 1) but is immediately reflected to propagate unhindered to regions of lower plasma density. A similar process occurs if the isoionic planes are aligned parallel to *BB'*, except that in this case the coupling occurs near $X = 1$ after the *Z* wave has been reflected; the corresponding ray path is shown in Fig. 3*c*.

The significance of the alignment of *AA'* and *BB'* is now clear —these are the orientations of the isoionic planes which render the coupling most efficient. It is seen from equation 1 that the coupling parameter ψ is also dependent on X^1 and therefore if X^1 is large one may expect some coupling to occur, even when the isoionic planes are not strictly aligned to *AA'* or *BB'*. Calculating the actual amount of coupling for different wave normal angles is the subject of further study.

Interpretation of observations

On the basis of the mechanism proposed, the frequency cut-offs appearing in the Imp 6 spectrogram (Fig. 1) can be identified. The lower cut-off at f_1 corresponds to the *Z*-mode cut-off ($X = 1+Y$) at the spacecraft; frequencies $<f_1$ will not reach the spacecraft, since they encounter cut-offs in the lower density regions above the spacecraft altitude. In fact, if f_1 is to correspond exactly to the condition $X = 1+Y$ at the spacecraft, some waves of this frequency must be incident normally on the isoionic plane, since waves incident obliquely will be reflected before reaching $X = 1+Y$. The Cerenkov radiation is expected to be produced with a fairly large range of wave normal angles since usually a wide range of particle energies is involved; the effect on the wave normal angle of varying β may be deduced from Fig. 3*a*. It is expected, therefore, that there will be a sufficiently broad distribution of wave normal angles to ensure that some of the waves come very close to the level $X = 1+Y$ before being reflected.

The other frequency cut-off at f_2 may be identified with the level $X = 1$ where the *O* wave is produced. At this level the *O* waves will have their normals mainly aligned to the geomagnetic field, this being a condition for their production. Thus one does not have a broad distribution of wave normal angles as for the *Z* mode and, theoretically, reflection of the *O* wave will occur before the level $X = 1$ is reached for the case shown in Fig. 3*b*. It is probable, however, that the region of coupling is so close to $X = 1$ that the cut-off at f_2 can be attributed to the *O*-wave cut-off at $X = 1$. This is also true if the coupling occurs after *X*-wave reflection (Fig. 3*c*).

From the identification of the cut-off frequency $f_2 = f_p = 6.35$ kHz, the plasma density at the spacecraft is calculated to be 0.5 electrons cm^{-3}, and if one uses the relation $X = f_p^2/f_1^2 = 1+Y = 1+f_g/f_1$, the electron gyrofrequency f_g at the spacecraft is found to be 2.3 kHz. The value of f_g at the spacecraft calculated from a harmonic expansion of the geomagnetic field is 2.2 kHz. A previous identification[1] assumed f_1 to be the plasma frequency and f_2 to correspond to the *X*-wave cut-off at $X = 1-Y$ (see Fig. 2). This resulted in an estimate of electron density of 0.35 electrons cm^{-3} and a gyrofrequency of 1.9 kHz. The maximum possible error from such a misidentification would amount to a factor of 2 in plasma density.

In the frequency range between f_1 and f_2, the electric field of the radiation should be predominantly perpendicular to the static magnetic field with the longitudinal component increasing rather rapidly near the plasma frequency[18,19]. With a single dipole antenna it is difficult to determine unambiguously the orientation of the electric field vector when the wave is linearly polarised, and a more detailed investigation of the spin-modulated noise between f_1 and f_2 using three mutually orthogonal antennae is required.

From the new identification of cut-offs presented here, the UHR frequency at the spacecraft is calculated to be $f_{\mathrm{UHR}} = 6.75$ kHz and the cut-off of the *X* wave should be at $f_X = 7.6$ kHz. These frequencies are indicated in Fig. 1, and they are seen to correspond to abrupt changes in noise intensity. The larger intensity <6.75 kHz is understandable since it is in this range $f_2<f<f_{\mathrm{UHR}}$ that the noise is believed to be produced by the Cerenkov mechanism. The fact that the intensity change occurs very close to the UHR, indicates that these waves have large wave normal angles, otherwise the intensity would have changed at a lower frequency corresponding to $X = (1-Y^2)/(1-Y_L^2)$ as may be deduced from Fig. 2.

It is tempting to identify the increase in intensity >7.6 kHz as being due to the presence of the *X* wave. There is no known mechanism for producing this mode locally but it is possible that it could have been formed by depolarisation of the *O* wave by reflections at the magnetosheath and at magnetospheric irregularities in plasma density. The resulting *X* waves could then propagate inwards and be reflected at the level $X = 1-Y$, thus producing an abrupt change in noise intensity at 7.6 kHz. The noise bands at higher frequencies would, however, remain unexplained.

An explanation of the noise bands usually observed close to the plasmapause as being harmonics of the local gyrofrequency has been ruled out, since the difference in frequency between bands in Fig. 1 is ~ 1 kHz whereas the gyrofrequency is > 2 kHz. It also seems that the noise bands are not accurately harmonically related. One possible explanation for these bands is that they are produced as a consequence of ionisation ducts below the spacecraft altitude. As is seen from equation 1, plasma density gradients within ducts would render coupling more efficient, X^1 being larger, and one could expect bands of more intense radiation at frequencies corresponding to the duct plasma densities. On this assumption and by using an average plasma density profile[1] for the magnetosphere, one can estimate the distance between ducts below the spacecraft to be $\sim 0.3 R_E$. It is significant that ducts are known to exist predominantly within the plasmasphere and the noise bands are usually seen close to the plasmapause.

Conclusions

It is concluded that mode coupling of Cerenkov radiation may be the source of terrestrial non-thermal radiation. The mechanism requires that the plasma be traversed by energetic particles and this is known to be the case in the magnetosphere. The angle between the geomagnetic field and the isoionic planes is an important parameter and this may explain the local-time asymmetry in the source location, since it is well known that the plasmasphere has a distinct outward bulge at local evening. In addition, the dawn–dusk magnetospheric electric field increases the local-morning electron energies (D. A. Gurnett, unpublished) by ~10 keV and this has obvious implications on the Cerenkov mechanism proposed.

The radiation which escapes to regions of lower plasma density will be in the ordinary mode which is left-hand polarised; polarisation measurements of the noise are not yet available. The radiation whose frequency is greater than the magnetosheath plasma frequency will escape into the solar wind; the radiation whose frequency is less than the sheath plasma frequency will be reflected and will be trapped between the higher plasma densities of the sheath and plasmasphere, ultimately escaping down into the magnetotail.

Conditions suitable for the mechanism proposed also exist in the morning magnetosheath, which is a favoured region for streaming electrons from the solar wind[20,21].

letters to nature

Type I supernovae and galactic production of iron

CURRENT models of galactic chemical evolution (see ref. 1) assume that heavy elements are produced by massive stars, that is, in type II supernova events. We show here that Fe may have a different source from other heavy elements—in type I supernovae which result from the deaths of moderately long lived stars.

Type I and type II supernovae both have similar radii and temperatures near maximum light[2], yet the spectra of type I supernovae show considerably more structure. Many of the lines have been attributed to Fe[3]. At a time long after maximum light, Kirshner and Oke[4] were able to study the emission from SN 1972e in NGC 5253 in a quantitative way. If their identification of Fe II lines is correct, $\sim 0.03 M_\odot$ of Fe is required. This is a lower limit to the Fe abundance and provides strong observational evidence for Fe production in type I supernovae.

Observations of type II supernovae at around maximum light do not show any overabundances of heavy elements. This is easily understood since the envelope of the presupernova star is being observed. The only observable material which has been recently processed by a massive star may be the fast moving knots in Cas A (refs 5, 6). Only lines of Ar, O, and S have been detected; no Fe lines have been observed although Fe II lines might be expected. No attempt has yet been made to put a limit on the Fe abundance. Thus, while there is no observational evidence for Fe production in type II supernovae, there is no evidence to the contrary. Stellar evolution calculations do not clarify the problem since it is unknown how much Fe is contained in the possible compact remnant of a supernova.

The last piece of evidence on Fe production comes from the theory of supernova light curves. First consider the supernova energy to be deposited instantaneously. If the observed supernova luminosity near maximum light is to be reproduced, the radius of the presupernova star must be $\geqslant 10^{14}$ cm (refs 7, 8). This condition is satisfied for massive stars, but may not be the case for the small mass progenitors of type I supernovae. If the initial radius is small, some supernova energy must be stored over tens of days. Colgate and McKee[8] have suggested that the energy is stored in the radioactive products of explosive nucleosynthesis. The model which reproduced the observed magnitude of type I supernovae produced $0.25 M_\odot$ of Fe. If any more Fe is produced explosively, the models predict excessive luminosity. It should be noted that the observed luminosity being reproduced in these models is based on a Hubble constant, H, of 100. A lower value of H would require greater Fe production. Thus, from observations and models of type I supernovae, their Fe yield is in the range of 0.03–$0.25 M_\odot$.

This yield can be compared with that required to give the present solar abundance of Fe. Using solar neighbourhood values for the birthrates of moderate-mass stars and galactic mass density, Ostriker *et al.*[9] derive limits on the Fe production per massive star. It is certainly $< 0.23 M_\odot$ of Fe per star and is very likely to be $< 0.023 M_\odot$ of Fe. The birthrate would be equivalent to the type II supernovae rate. Tammann[10] finds that types I and II supernovae have similar total rates and radial distributions in galaxies like our own. Thus the yield found by Ostriker *et al.* also applies to type I yields.

These considerations indicate that even the observed amount of Fe in type I supernovae may be sufficient to give the Fe abundance in the solar neighbourhood. If the low Fe production per supernova is correct, the radioactivity model for type I supernovae is incorrect, and models with either extended initial envelopes or another form of late energy input must be considered.

Fe production in type I supernovae has implications for the chemical history of the Galaxy. It is generally accepted that type I supernovae result from less massive stars than those giving type II supernovae (for a recent review, see Tinsley[11]). The lifetimes of the pre-type I supernovae stars may be an order of magnitude longer than that of the pre-type II supernovae stars. Assume that the stellar mass function is independent of time. During the initial burst of star formation, there is a lag between the production of Fe in type I supernovae and the production of the other heavy elements in type II supernovae. During this period, stars can be formed which are underabundant in Fe relative to the other heavy elements. There is some evidence that old stars are overabundant in O relative to Fe (ref. 12), but the observed abundances may not reflect the initial composition of these stars. Peimbert[13] notes that the O overabundance may well be primaeval. He also reviews evidence that at least two parameters are required to describe the horizontal branch characteristics of globular clusters and suggests that the two parameters are the Fe abundance and the CNO abundance.

If considerable heavy element processing occurs in the disks of spiral galaxies, the type I supernova origin of Fe is of some importance. Observations of supernovae show that type II supernovae are concentrated in spiral arms while type Is are scattered throughout the disk[14]. A given volume of gas thus receives processed material from type II supernovae in bursts and material from type Is more uniformly. The result is that the ratio of Fe to other heavy elements may be expected to show fluctuations.

Heavy elements are overabundant in cosmic rays in a way that is consistent with the supernova origin of cosmic rays. Ramaty *et al.*[15] found that the energy spectrum of Fe cosmic rays is flatter than that of CNO nuclei. They interpret the result as indicating that Fe nuclei are accelerated near to a pulsar while the other heavy elements are accelerated in the surrounding nebula. The present work suggests a different interpretation: Fe nuclei are accelerated in type I supernovae and CNO nuclei are accelerated in type II supernovae. If a Fermi-type acceleration mechanism is operating, the flatter Fe energy spectrum may arise from the higher material velocities in type I supernovae.

In the future, observational checks on the source of galactic Fe will be possible. Clayton[16] has reviewed arguments that Fe is produced explosively and claims that γ-ray line observations of supernovae will enable abundances of nucleosynthesis products to be determined. Also, young supernova remnants such as the remnant of Tycho's supernova of 1572 should be examined for the presence of Fe emission The supernova ejecta may have been heated to high temperature in a reverse shock wave or a conduction front, so that X-ray observations with high spectral resolution may be the most profitable. Third, observations of extragalactic supernovae, particularly at late times, will be useful. These observations should yield information on whether type I supernovae are important contributors of galactic iron.

X-ray emission from γ Cas

THE Copernicus orbiting observatory contains two astronomical experiments, the Princeton ultraviolet spectrometer and the MSSL X-ray package. They are coaligned, and during ultraviolet observations the 3–8 keV collimated proportional counter routinely collects background data[1] When the observatory was pointed at the ultraviolet target γ Cas on December 21, 1975 and again on January 20, 1976, a clear excess of counts was seen in the 3–8 keV channel compared to preceding and following targets. This count rate corresponds to a flux at the Earth of $\sim 1.2\times10^{-10}$ erg cm^{-2} s^{-1}, and lies 5σ above the mean background level determined from several weeks of observations (Table 1)

We have also examined earlier Copernicus X-ray data taken on γ Cas The star was observed on November 4, 1973 and on November 13, 1974. No flux was detected during the 1973 observation, but the sensitivity attainable was low because of the sparsity of background data near that time A signal was detected in 1974, 4σ above the mean background.

The FWHM field of view of the Copernicus X-ray detector is $\sim 3°$, and we cannot localise the emission to greater accuracy than this. Jernigan[2] has, however, reported that the SAS-3 satellite, in a 2-d observation beginning December 30, 1975, observed X-ray emission of comparable intensity to that reported here from a region of sky within 1′ of γ Cas. This suggests a high probability that the X-ray emission originates from the vicinity of this star, although we note that γ Cas does have a companion ADS782B ($m_v \approx 10$), the two stars being separated by ~2″ (ref. 4). The X-ray source was not detected before November 1974; in particular, it was not recorded in the Uhuru sky survey[3,4], which suggests that it is variable. There is no evidence within the Copernicus data for flux variations $>1\sigma$, but the strength reported by the SAS-3 group[2] ($3\ 5\times10^{-10}$ erg cm^{-2} s^{-1} from 2–11 keV) is a factor of ~ 1.5 above the highest value seen by Copernicus, allowing for the difference between the energy range of the two detectors.

γ Cas is an extreme Be star whose magnitude is variable between 1.6 and 3.0 (ref. 4). Its absolute visual magnitude is probably ~ -4 (ref. 4), so that the intrinsic luminosity of the X-ray source is $\sim 10^{32}$ erg s^{-1}. Maraschi, Treves and van den Heuvel[5] have noticed the several coincidences

Table 1 X-ray data from γ Cas

Observations Mid-time	Duration (h)	c.p.m. (3–8 keV)	erg cm^{-2} s^{-1} ($\times 10^{-10}$)
1973 November 4.4	16	<3.0	$<1\ 2$
1974 November 13 7	37	2.0 ± 0.5	0 8
1975 December 21 6	12	$3.3\pm0\ 6$	1 3
1976 January 20 4	22	$2.8\pm0\ 5$	1.1

The uncertainties in counting rate are dominated by systematic background effects which are measured empirically. The energy flux is derived assuming a Crab-like spectrum, but the conversion factor from c p m to erg cm^{-2} s^{-1} is relatively insensitive to spectral slope and form.

between Be stars and X-ray sources. In particular, γ Cas is very similar in its optical characteristics to X Per (ref. 4), which has been associated with the regularly varying X-ray source 3U0352+30 (refs 6–8). The ratio of X-ray to optical luminosity of the two stars now differs by just over an order of magnitude[8]. No evidence is found for regular modulation in the present data between 2 and 40 min. The source is, however, comparatively weak, and any modulation of peak to mean amplitude <60% of the mean flux would have gone undetected. More sensitive observations will be necessary to explore further the possible parallels between γ Cas and X Per Meanwhile, γ Cas provides yet another example of the growing number of intrinsically relatively weak X-ray sources being discovered which are associated with nearby stellar objects (see ref. 9).

Radiometric diameter and albedo of the remarkable asteroid 1976AA

THE minor planet 1976AA (Fast-Moving Object Helin), discovered on January 7, 1976, is the first asteroid found with an orbital period of < 1 yr (orbital elements $a=0.97$, $e=0.18$; $i=19°$; ref. 1). Although it seems to be a likely speculation that 1976AA is a former Apollo object that originally had its aphelion in the main asteroid belt, it is possible that this object is a member of a group of minor planets that is distinct in physical as well as orbital properties. Observations that reveal the physical nature (colour, albedo, texture, mineralogy) of its surface are needed to compare it with better studied objects in more orthodox orbits. This letter reports a determination by infrared radiometry of the diameter and albedo of 1977AA.

The radiometric technique of measuring diameters and albedos was first applied to asteroids in 1970 (ref. 2) and has recently been discussed in some detail[3,4]. Physically, it is based on the dependence on albedo of the balance between reflected and thermally emitted radiation for an airless body in thermal equilibrium with the sunlight striking it The application reported here follows the formulation and calibration by Jones and Morrison[4], which has previously been used to determine the diameters of > 60 main-belt asteroids[5,6] and the Earth-approaching object 433 Eros[7].

The observations were made on January 26, 1976 in a broad spectral band centred at ~ 10 μm with the infrared photometer[8] of the 1.5-m telescope of the Lunar and Planetary Laboratory Catalina Observatory. The primary stellar standards were α Tau and β Gem, for which we adopted magnitudes of -3.1 and -1.3, consistent with the standard calibration assumed for the radiometric diameter technique[5]. Two groups of integrations, centred at UT dates 26.22 and 26.30, yielded a 10-μm magnitude of $+5.0\pm0.3$. At the time of observation, 1976AA was 0.150 AU from Earth and 1.075 AU from the Sun, and its phase angle was 50°. Although it is not clear exactly how the radiometric brightness should be reduced to full phase, both model calculations and observations of 433 Eros[7] suggest a correction of between -0.01 and -0.02 mag deg^{-1}, yielding an equivalent 10-μm magnitude at zero phase of $+4.3\pm0.5$. The value of $V(1,0)$, the zero-phase, unit-distance visual magnitude, is $+17.6$ from other observations made here (J.C.G., unpublished).

A straightforward solution for diameter and visual geometric albedo based on these observations yields $D=900\pm200$ m and $p_V=0.20\pm0.07$. This albedo is in satisfactory agreement with a preliminary polarimetrically derived value (J. C. Gradie, unpublished), and the diameter is the smallest ever measured for an asteroid.

On the basis of its albedo, 1976AA can probably be classed with the stony or silicaceous (S-class) group of asteroids[9]. These asteroids seem to have related surface mineralogies and to be the predominant type near the inner edge of the belt, although the much darker carbonaceous objects constitute the great majority of all asteroids. The previously studied Mars- and Earth-orbit-crossing objects—433 Eros, 887 Alinda, 1566 Icarus, and 1685 Toro—also belong to the broad S compositional class. Thus, on the basis of this preliminary physical datum, 1976AA appears similar physically to other small asteroids that approach the Earth.

This research was supported in part by grants from NASA. We thank E Helin for informing us of the existence of 1976AA, and J. G. Williams for providing the ephemeris without which these observations could not have been made.

On simultaneous tilt and creep observations on the San Andreas Fault

THE installation of an array of tiltmeters along the San Andreas Fault[1] has provided an excellent opportunity to study the amplitude and spatial scale of the tilt fields associated with fault creep. We report here preliminary results from, and some implications of, a search for interrelated surface tilts and creep event observations at four pairs of tiltmeters and creepmeters along an active 20-km stretch of the San Andreas Fault. We have observed clear creep-related tilts above the instrument resolution (10^{-8} rad) only on a tiltmeter less than 0.5 km from the fault. The tilt events always preceded surface creep observations by 2–12 min, and were not purely transient in character

Although episodic fault creep has been observed at many locations of the San Andreas, Hayward, Calaveras, and other active faults in the San Andreas Fault System[2–8],

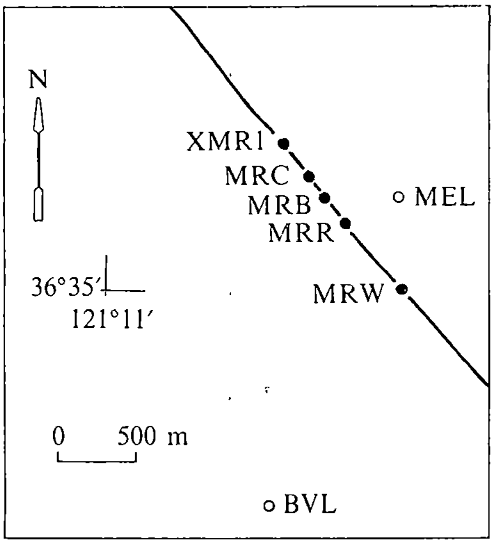

Fig. 1 Location map in the Bear Valley region of central California of tiltmeters (MEL and BVL) and creepmeters (MRW, MRR, MRB, MRC and XMR1) along the San Andreas Fault.

measurements of transient tilts and strains associated with creep events have not yet been made in sufficient detail to allow estimates of critical parameters such as depth, dimension, amount of slip, and the effects of material property variations. These parameters are critical to questions concerning, first, the degree to which the dynamic aseismic slip behaviour of the fault is reflected in fault creep measurements; second the relationship between observed creep and seismicity; and third, the source of the nonlinear form of the creep signals. Typical creep events have amplitudes of a few millimetres and durations of a few minutes to a few days[8,9]. Fault displacements inferred from cumulative creep[10] are in approximate agreement with those measured using geodetic techniques[11], and approximately simultaneous observations of creep events at closely spaced creepmeter sites have been interpreted as slip propagation along the fault at rates of up to 10 km d^{-1} (refs 4 and 6).

With one exception, the tiltmeters considered here form part of an array of shallow borehole instruments approximately 6 km apart, and 1–2 km from the fault (Fig. 1), intended primarily for the detection of earthquake related deformation[1] The exception is the tiltmeter at Melendy Ranch (MEL) which was installed 370 m from the fault near several Melendy Ranch creepmeters This instrument grouping, in addition to tiltmeter MEL on the north-east side of the fault, consists of creepmeters XMR1, MRC, MRB, MRR, and MRW along the fault from north-west to south-east, and tiltmeter BVL on the south-west side of the fault, as shown in Fig 1. At these creepmeters clear examples of episodic creep on the San Andreas Fault are observed every few months[8,9].

Since January, 1974, three of the largest creep events, each recorded on at least two creepmeters, have occurred while both tiltmeters were operating. Figure 2 shows about 6 h of parallel record from the two tiltmeters and the particular creepmeters in operation at the time of these creep events The uncertainty in timing for all sets of records is less than 2 min.

For the first creep sequence of July 11, 1974 (Fig. 2*a*) creep was recorded only on meters MRC and XMR1 to the north-west of MEL The times of onset were 1745 and 1808 GMT, respectively. For more than an hour before 1743 a ramp-like change is evident in the north–south tilt component at MEL (Fig 2*a*). Although interesting, this is the only example of a tilt ramp of this sort, and its meaning is not clear. From 1743 to 1800 the tilt at MEL increased by 0 5 μrad in a direction S41°W. The amplitude decreased and the direction changed slowly clockwise during the next 30 min, finally resulting in a tilt of 0.4 μrad towards the west No significant changes occurred in the tilt record at BVL (resolution 10^{-2} μrad) during this time.

A second creep sequence, on October 3, 1974 (Fig. 2*b*), is more important since it was observed on the four creepmeters MRW, MRB, MRC, and XMR1 along the fault from the south and to the north-west of MEL. The first onset of creep occurred at 0812 at MRC Almost simultaneous offsets occurred next at MRW and MRB at 0815 followed by XMR1 at 0837. The tilt changed at MEL between 0800 and 0815 by 0.52 μrad in a direction S72°W, and during the next hour this amplitude decreased and the direction changed slightly clockwise until reaching a final tilt offset value of 0.36 μrad in a westerly direction. The tilt records at BVL were again unchanged.

The creep sequence on April 14, 1975 (Fig 2*c*) was recorded on MRR at 0805, followed by MRC at 0821 and on XMR1 at 0826. Only the east–west tilt component was operating at MEL during this time This record shows a tilt change of 0.25 μrad between 0800 and 0807 similar to that observed for the earlier creep sequences.

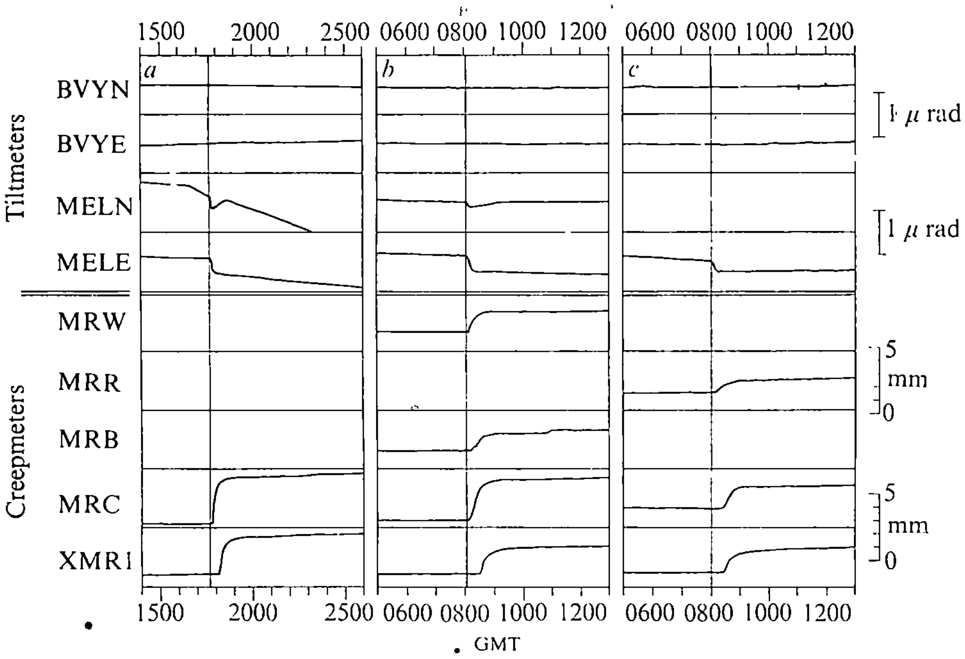

Fig. 2 Three examples of approximately 6 h of simultaneous digitised records from creepmeters XMR1, MRC, MRB, MRR and MRW and tiltmeters BVL and MEL during creep events on: *a*, July 11, 1974, *b*, October 3, 1974; *c*, April 14, 1975. BVLN, MELN, and BVLE, MELE are the north and east components, respectively Absence of data indicates an instrument malfunction

For the next pair of instruments to the north, creepmeter XFL1 and tiltmeter SAS with a 2-km separation, five creep sequences have occurred since June, 1973 when simultaneous recording began. Tiltmeter SAS is 1.2 km from the fault. At that distance, as for BVL, no clear relationship between the creep events and either short or intermediate term tilts has been found. This is true also for the northernmost instrument pair considered, creepmeter XPR1 and the tiltmeter LIB, separated by 3.4 km with LIB 1.5 km from the fault.

Creep-related tilts seem, therefore, to be rapidly attenuated as a function of distance from the fault. At Melendy Ranch, in particular, a displacement of a few millimetres on the fault that results in a tilt of 0.5 μrad at 370 m and less than 0.01 μrad at 1,500 m implies at least inverse cube attenuation with distance. This may be expected from either a small scale or shallow source or a slightly decreased rigidity in or near the fault zone. The latter possibility seems most likely since the surface displacements extend at least 1.2 km along the fault trace for the Melendy observations and seem in other cases to extend to several tens of kilometres[6]. This would also explain why a search for interrelationship between short period tilt changes on adjacent tiltmeters has so far been inconclusive.

The tilt signals for all three events are similar and therefore indicate a similar source process. The residual west tilt observed at MEL for the creep events, and the general systematic later arrivals and lower amplitudes of these and other creep events between MRC and XMR[8,9], indicate that the slip amplitude and/or the propagation velocity probably vary as the events propagate. Even with decreasing propagation velocity and slip amplitude to the north, however, the form of the tilt and the nearly simultaneous onset times for tilt and creep during the October 3 event (Fig. 2*b*) are difficult to fit with a single simple model of horizontal slip propagating northwards. The introduction of a vertical slip component (south-western side up) over a limited extent of the fault with a local maximum between MRB and MRC, together with horizontal slip, can generate time histories similar to those observed. The accumulated vertical displacement necessary as a consequence of this model is indicated by the presence of a north-easterly-facing scarp along the fault trace from MRW to MRC, with increasing scarp height to the north-west (the point of maximum development is about 3.5 m between MRB and MCR).

Most records of other creep events at Melendy Ranch display regular patterns of onset times[8,9] although variations similar to those for the October 3 and April 14 events occur. Simple slip models, such as indicated above, are not always compatible with the detailed onset times and the creep amplitudes. It is possible that the exact onset times of creep, and perhaps also the amplitudes, result from, or are modified by, the particular local failure conditions of the surface material. More examples on a supplemented tilt and strain array in this area should clarify many of these details and make a rigorous inversion possible.

We thank Bill Stuart and Wayne Thatcher for critically reading the manuscript. A more complete discussion will be held elsewhere.

Compression and crustal shortening in Andean-type orogenesis

CONTROVERSY exists as to the role of crustal compression and shortening in the formation of the easterly-directed thrust system in eastern portions of the North American Cordilleran orogen[1,2]. In fact, the controversy can be extended to the general issue of the presence or absence of crustal shortening in any major phase of the development of that orogen. Opponents of crustal shortening have suggested that most fold and thrust structures of the Cordilleran orogen can be explained by gravity-induced stresses[3,4].

Tectonic analogies between the modern central Andes and the US Cordillera of Mesozoic and earliest Tertiary age have been discussed by Hamilton[5,6], James[7], and others. The Andes, a chain characterised by voluminous magmatic activity, are bounded on the west by the Peru–Chile trench, a zone of ongoing plate convergence, and on the east by an active fold and thrust belt which separates orogen from craton. Rates of subduction are of the order of 7–12 cm yr^{-1} (ref. 8), and can reasonably be extrapolated back at least into the late Miocene on the basis of marine magnetic anomaly studies[9]. Since Middle Miocene time the central Andes, including Peru, have experienced intensive igneous activity and accompanying orogenesis[10]. Folds, reverse faults and thrust faults of eastward vergence have developed along the eastern margin of the Andes in the Sub-Andean zone (Fig. 1). The Andes were lifted up to their present height during this late Cainozoic episode of orogenesis.

Stauder[11] in a study of seismicity in the Peruvian Andes, has concluded that the Nazca Plate is thrusting under the South American plate beneath central and northern Peru along a surface of shallow (10–15°) dip. Of particular importance to an understanding of Andean orogenesis is Stauder's additional conclusion that the leading (western) edge of the South American plate is under east–west horizontal compression for a distance of approximately 700 km east of the Peru Trench (Fig. 1). Numerous hypocentres are present in that plate at depths of 1–90 km and for distances up to 700 km east of the trench. Most lie at distances from the trench of 200 to 600 km, depending on latitude. Focal mechanisms for 9 or 10 of these intraplate earthquakes yield horizontal compressive stress axes oriented approximately east–west. Three solutions indicate predominantly strike-slip faulting and six indicate reverse dip-slip faulting.

Middle Miocene to Recent central Andean structural and magmatic features can best be explained by the effects of convergence of the Nazca oceanic plate toward and beneath the South American Plate. Magma genetically related to subduction of the Nazca Plate has intruded the leading edge of the South American lithosphere and led to its thermal weakening. Deformation in response to east–west horizontal compression is localised in the plate margin region of elevated temperature where the lithosphere yields variably by fracture and flow. Compressive thickening of the leading edge can account for the uplift of the Andean Chain. The Sub-Andean fold and thrust belt thus marks the present eastward limit of intraplate deformation resulting from subduction of the Nazca Plate. Gravity may have

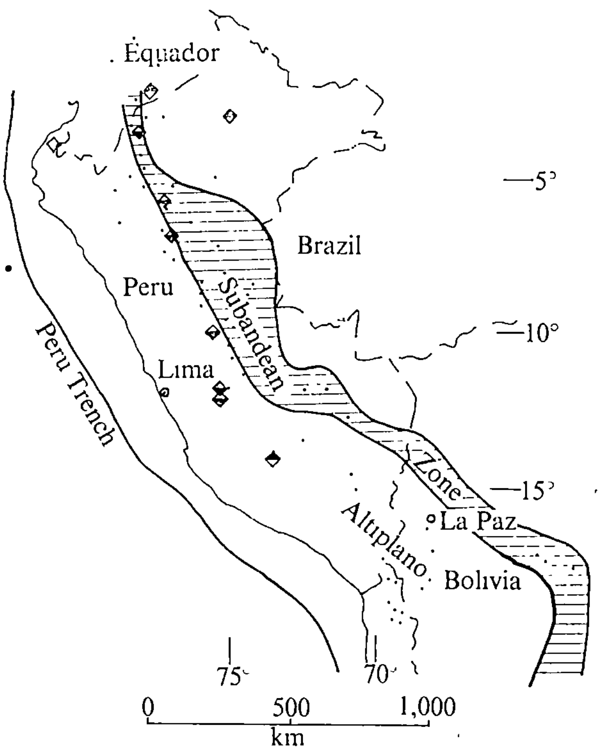

Fig. 1 Epicentres of shallow focus (1–70 km) earthquakes in the central and eastern part of the Peruvian sector of the Andes for 1961–68. Diamonds, earthquakes analysed by Stauder[11]; diamonds with blackened upper half, strike-slip solution; diamonds with blackened lower half, reverse fault solution; open diamonds, solution for north–south compressive stress and reverse faulting.

a minor role in the tectonic development of the Andean Orogen, but it is secondary relative to lithospheric compression and shortening.

The geological history of the Mesozoic and early Cainozoic Cordilleran orogenic belt of western North America suggests it developed in a structural setting much like that of the modern Andes. Key questions about the origin of the Cordilleran belt concern the role of horizontal compression in crustal deformation, particularly in the formation of the foreland or marginal fold and thrust belt which, before Tertiary basin-range extension, lay up to 800 km east of the convergent plate margin. Stauder[11] has concluded that the leading edge of the South American Plate beneath the Andes is under horizontal east–west compression for a distance at least 700 km east of the Peru Trench. His data demonstrate that crustal compression and shortening are possible in an Andean structural setting far from the offshore plate boundary, and support a compressive origin for older Cordilleran structures analogous to those of the central Andes.

Caledonian magmatic activity in south-eastern Greenland

THE position of the Caledonian front in eastern Greenland is important[1,2] in any reconstruction of the pre-drift North Atlantic (see ref. 3). No evidence of any Caledonian activity has yet been found south of Scoresby Sund, however, where the Caledonian Front, exposed in Gåseland[4], is seen to pass under the thick plateau basalts of Kong Christian den IX's Land[5]. South of the basalts, only Precambrian ages have been obtained[2]. We report here on a complex of Caledonian age in the Kangerdlugssuaq district, which lies about 300 km to the south of the Gåseland exposures. Unknown Caledonian events may be recorded in basement rocks of the areas, and may be uncovered by more detailed investigation. Moreover, petrological similarities between the new complex and the alkaline suite found in Assynt, north-western Scotland, may provide a further link in the North Atlantic jigsaw puzzle.

We have had access to specimens from the Batbjerg Intrusion at the head of Kangerdlugssuaq and have published a description of leucite from this locality, along with a map showing its location and approximate extent[6]. The rocks were believed to be Tertiary, in common with those of the nearby Gardiners Plateau Intrusion (which it resembles in many aspects)[7] and other plutonic rocks of the area[5]. It was not until a visit in the summer of 1975 by a combined expedition from the Universities of Copenhagen and Toronto that many of the rocks in the Batbjerg Intrusion were found to be deformed and thus unlike the Tertiary rocks of the district. The impression that this complex is different from the nearby Tertiary rocks is confirmed by the new radiometric ages of around 440 Myr (Table 1). The dated rocks were selected as having primary magmatic textures, and we believe that the ages indicate crystallisation from a magma at the time of the Caledonian Orogeny.

In Scotland, alkaline rocks of a similar age[8] occur in the Assynt district. In particular, the Loch Borolan laccolith[9] is a layered complex of melanite pyroxenites, nepheline syenites and nordmarkitic syenites. Characteristic minerals are melanite garnet, acmitic diopside, green 'biotite', and rounded aggregates, interpreted as pseudoleucites.

Preliminary examination of the Batbjerg rocks shows that the bulk of the complex is composed of pyroxenites containing acmitic diopsides (an analysis has been presented in ref. 6), olivine, mica (sometimes green) and apatite. Other rocks include folded and sheared dunites, melteigitic rocks containing leucite and melanite, and a net-veined complex of syenitic dykes, some undersaturated, some granitic, cutting the pyroxenites. Many volcanic necks with associated cone sheets and ring dykes cut the surrounding gneisses, but they show extensive uralitisation of the pyroxenes and may be foliated. Masses of metamorphosed limestone (some with crinoid fragments) and quartzites occur along the contact between the pyroxenites and the gneisses They are interpreted as screens of country rock which have sunk from above.

It is clear that, superficially at least, there are many petrological similarities between Batbjerg and Loch Borolan. A speculative possibility is that the calcareous sediments at Batbjerg are equivalent to the Durness limestone and quartzites at Assynt, which had such a prominent role in Shand's now unpopular hypothesis for the development of the undersaturated rocks, both at Borolan and in

Table 1 Radiometric and petrographic data for the Batbjerg Complex, Kangerdlugssuaq

a Rb/Sr data

Sample	$^{87}Rb/^{86}Sr$*	$^{87}Sr/^{86}Sr$†
NM 3206/5 Diopside	0.00303 ± 0.00002	0.7046 ± 0.0003 (unspiked)
NM 3209 Phlogopite	28.4 ± 0.2	0.8819 ± 0.0006 (spiked)
NM 3206/5 Phlogopite	56.6 ± 0.4	1.0494 ± 0.0006 (spiked)

b K/Ar data

NM 3209	Phlogopite	^{40}Ar rad (standard cm^3 g^{-1} × 10^{-4})	1.4712	(mean of 2 determinations)
		^{40}Ar rad (%)	98.4	(mean of 2 determinations)
		K_2O (%)	9.54	(mean of 6 determinations by atomic absorption)
		Age (Myr)	446 ± 13	

c Petrographic notes

NM 3209	Dark pegmatitic pyroxenite with abundant brown phlogopite
NM 3206/5	Bright green, friable pyroxenite with about 10% pale greenish phlogopite

Both rocks are free from deformational fabrics and felsic minerals.

* Errors on $^{87}Rb/^{86}Sr$ ratios determined from 10 duplicates.

† Errors on $^{87}Sr/^{86}Sr$ ratios determined from 19 unspiked duplicates and 10 spiked duplicates.

Using $\lambda_{Rb} = 1.39 \times 10^{-11}$ the York-1 model provides an age of 443 ± 14 Myr with an initial $^{87}Sr/^{86}Sr$ ratio of 0.7046 ± 0.0016 (ref. 2). Standard errors include a 'Student's *t*' multiplier based on results for 10 duplicates.

other parts of the world[10]. Detailed petrological and mineralogical studies are at present being carried out on the Batbjerg rocks and will be published elsewhere. They should allow a more reliable comparison between the two intrusions. The gneisses surrounding the Batbjerg Intrusion are cut by an immense number of volcanic vents and associated dykes and cone sheets. The vents range in size from a few metres to perhaps half a kilometre in diameter and represent a further point of similarity to the Scottish and Irish Caledonides, where similar volcanic bodies, assigned to the appinite suite, are widespread[11,12]. Like the appinites, the Batbjerg vents are rich in hornblende and were emplaced by highly explosive, volatile-rich magmas.

An important question to be asked is, how widespread is Caledonian activity in the Kangerdlugssuaq district and further to the south? Existing radiometric ages from the gneissic basement of the area, which include K/Ar, $^{40}Ar/^{39}Ar$, Rb/Sr mineral and whole rock ages[2,13,14], give ages ranging from ~ 1,700 to 2,700 Myr. Sampling has not, however, been carried out with radiometric dating in mind, and no systematic mapping of the basement has yet been made. It is clear that a great deal more detailed work of this nature must be undertaken before the history of the basement can be unravelled with any certainty. In recent years it has become clear that old ages frequently occur in younger fold belts as evidenced by, for example, the 3,000 Myr isochron reported for samples from within the Caledonides of the Scoresby Sund district[15].

It is tempting to speculate that the close spatial association of similar rock types with widely differing ages is not coincidental. Thus, the Batbjerg Intrusion was originally regarded as Tertiary[6] largely because of its petrological similarity to the Gardiners Plateau Intrusion which cuts Tertiary plateau basalts and is not more than 10 km distant. The Tertiary age of the Gardiner Intrusion is confirmed by an unpublished fission track age of 54.8 ± 3.4 Myr (A. G. W. Gleadow, personal communication). It comprises ultramafic rocks (dunites, pyroxenites and melilite rocks or uncompahgrites) with smaller amounts of nepheline syenites, urtites and related rocks. As such it falls into the general category of alkaline ultramafic complexes, to which the Batbjerg Intrusion is also assigned.

A possibility which should be explored, probably by means of isotopic studies, is that the origins of both intrusions are attributable to an alkali-enriched upper mantle which has underlain this area for several hundreds of millions of years, a possibility that has been suggested in other cases Thus, it is now becoming clear that many ultramafic nodules in lavas apparently preserve an isotopic record of earlier mantle events. For example, Burwell[16] has recently reported nodules from Australia which lie on an isochron of about 700 Myr. That date coincides with a period of plate convergence similar to that in the North Atlantic during Caledonian times.

Until this report of Caledonian rocks in the Kangerdlugssuaq district, there has been no basis whatsoever for showing the Caledonian front in eastern Greenland passing out into the Denmark Strait near the mouth of Kangerdlugssuaq Fjord, as has been done by Flinn[3]. Indeed, rocks from the only basement exposure to the east of this line had already been reported to have radiometric ages of over 2,000 Myr. In the light of these considerations, it must be concluded that the position of the Caledonian front in this area is unknown and cannot therefore be used for pre-drift reconstructions. The discovery of rocks of Caledonian age in the Kangerdlugssuaq district indicates, however, that preconceived ideas on the basement rocks of southern Greenland are not necessarily correct. It is clearly desirable to carry out further work on the basement in that region.

We thank Ole Larsen and D.C. Rex for age determinations (Table 1). The field work was supported by the Danish Natural Sciences' Research Council and the National Research Council of Canada. Preliminary samples were put at our disposal by the Northern Mining Company, Copenhagen.

J. D. Friderichsen and A. K. Higgins of the Geological Survey of Greenland have offered valuable comments.

Na, P, Ti and coordination of Si in garnet from peridotite and eclogite xenoliths

THEORY and experiment show that some cations are surrounded by extra oxygen anions at elevated pressure: for example, Si changes from 4-coordination in quartz and coesite to 6-coordination in stishovite. Sobolev and Lavrent'ev[1] suggested that substitution of Na in garnet derived from the mantle is coupled with 6-coordinated Si according to the equation $Ca^{VIII}+Al^{VI}\rightarrow Na^{VIII}+Si^{VI}$. We show here from sensitive electron-microprobe analyses that Na in garnets from ultramafic and eclogite xenoliths can be explained by coupled substitutions with Ti and P without invoking 6-coordinated Si.

Table 1 records mean values for simultaneous electron-microprobe analyses of selected garnets using a strong electron beam and long counting times. Backgrounds were carefully estimated at several wavelengths above and below the peak, and the standard deviation of individual analyses is 15–25 p.p.m. Cracks and surface blemishes were avoided during analysis with a 70-μm diameter spot, and 20 out of 21 garnets were found to be homogeneous from analyses at 3–6 places. Standards were $Di_{85}Jd_{15}$ glass (Na), A408 apatite (P) and Corning V glass (Ti). The correction factors for Na and Ti were trivial and were ignored, but correction factors for P were applied from the GLAB program (L. W. Finger, personal communication) using major-element concentrations from solid state detector and spectrometer analyses with a 2-μm diameter electron beam.

The concentration ranges for Na_2O (100–1,400 p.p.m. by weight) and TiO_2 (210–7,800) do not exceed those given previously for Na in garnets associated with diamond[1] and Ti in garnets from peridotite and eclogite xenoliths[2]. The range for P_2O_5 (160–940) is within that for garnets synthesised from basaltic melts at 1.8–4.5 GPa (18–45 kbar) pressure[3]. No previous analyses of P_2O_5 in mantle-derived garnets have been reported.

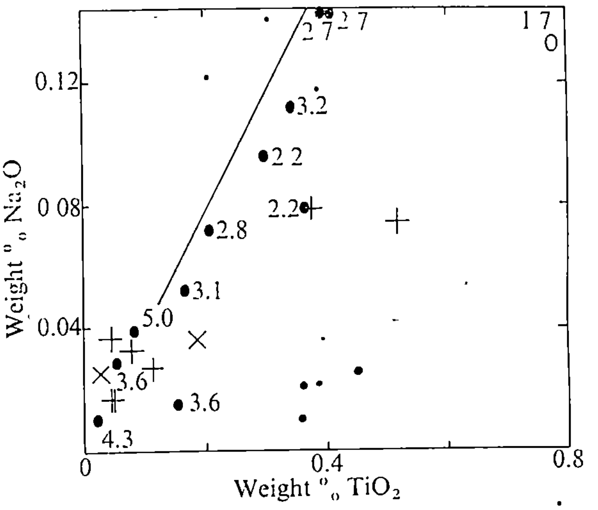

Fig. 1 Weight % Na_2O against TiO_2 in mantle-derived garnets: +, garnet–lherzolite; ×, other ultramafic rock; ●, eclogite; ○, diopside megacryst with garnet and sulphide inclusions. The numbers are K_D as defined in Table 1 for the eclogites. The straight line represents equal atomic concentrations of Na and Ti.

The Na concentration generally increases with the Ti concentration (Fig. 1), and in all but six garnets, atomic Ti exceeds atomic Na. A rough correlation exists also between Na and P, but the spread is well outside the analytical error band. In all but one garnet atomic Na exceeds atomic P.

Because atomic Na is always less than atomic (Ti+P), there is no need to invoke 6-coordinated Si (Fig. 2). Substitutions of the type $Ca^{VIII}+Si^{IV}\rightarrow Na^{VIII}+P^{IV}$ and $Ca^{VIII}+Al^{VI}\rightarrow Na^{VIII}+Ti^{VI}$ retain the normal valence and coordination number of Si, Ti and P. Thilo[4] reported garnet structure for $Na_3Al_2P_3O_{12}$ and $NaCa_2Mg_2P_3O_{12}$ compositions. Ringwood and Lovering[5] suggested that $(CaNa_2)Ti_2Si_3O_{12}$ and $(Ca_2Na)(AlTi)Si_3O_{12}$ are the probable Na-bearing components in garnet synthesised from a clinopyroxene–ilmenite nodule at pressure > 10 GPa. Although 6-coordinated Si may occur in the lower mantle as stishovite (see ref. 6), there is no evidence for its existence in minerals ejected to the Earth's surface from the upper mantle.

Table 1 Analyses of mantle-derived garnet

Label	Host rock*	Location	Weight TiO_2 (p.p.m.)	P_2O_5 (p.p.m.)	Na_2O (p.p.m.)	K_D

K_D = (FeO/MgO)gt/(FeO/MgO)cpx.
* All garnet lherzolite, pyroxenite and wehrlite host rocks exhibit granular texture.

The validity of geothermometers and geobarometers involving pyroxene and garnet is controversial, but the parameter $K_D = (FeO/MgO)gt/(FeO/MgO)cpx$ has been used to classify eclogites on a probable depth basis (see ref. 7), and has been shown from laboratory syntheses[8] to decrease with increasing temperature and decreasing pressure. There is a weak tendency for Na, Ti and P in the garnets from eclogites to increase as K_D decreases (for example in Fig. 1), which might suggest that substitution of these minor elements in garnet increases with the depth of formation. Elsewhere we show that the correlation between K_D and Na_{gt}/Na_{cpx} for lherzolites and eclogites is good. Much further work is needed on the factors which control the substitution of minor and trace elements in mantle minerals, especially because partial melting should lead to strong fractionation.

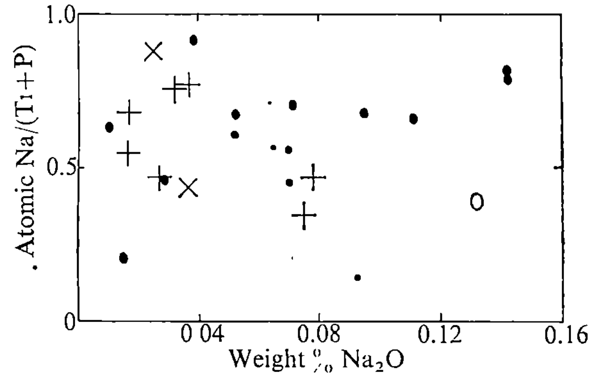

Fig. 2. Weight % Na_2O against atomic Na/(Ti+P). See Fig. 1 for symbols.

Tree growth and climatic cycles in the rain shadow of the Grampian mountains

TREE-RING widths have been widely studied as a guide to historical meteorology[1,2], the assumption being that fluctuations superimposed on the smooth progression of change with age are climate induced. Several authors[3,4] have even identified cyclical patterns in tree growth, some of which they have tentatively linked to sunspot activity, but generally the precise climatic parameter that may be operating remains unspecified. In Scandinavia, ring widths seem to fluctuate with summer temperature[5,6], although precipitation during early summer may also be influential[7]. In Scotland, on the other hand, Schove and Frewer[8] were unable to relate any meteorological character to the growth pattern of native Scots pine (*Pinus sylvestris* L.) on Speyside. Here we report, however, that examination of the results from two long term fertiliser experiments in mature Scots pine at Alltcailleach forest (National Grid Reference NO 3596), on upper Deeside, has shown that growth exhibits several regular oscillations each of which can be related to a particular climatic cycle. Furthermore, it would seem that some of these climatic cycles may be limited to low rainfall areas, such as the rain shadow of the Grampian mountains.

Table 1 Correlations between ring width deviation, May rain during the same year, annual temperature during the same year and rain during May plus June of the previous year

	D	$M^{0.1}$	T	MJ
D	—	0.453	0.379	0.423
$M^{0.1}$	$P < 0.01$	—	−0.095	0.176
T	$P < 0.05$	NS	—	0.220
MJ	$P < 0.01$	NS	NS	—

The trees, planted in 1883 on a freely drained humus iron podzol developed on a terrace of the river Dee, remained virtually unthinned until 1934. Since then numerous light thinnings have been carried out at no fixed interval. In late 1972 increment cores were drilled from opposite sides of 32 untreated trees and the width of each of the 40 outermost rings measured to the nearest 0.01 mm. Meteorological data used is that published[9] for Balmoral (~10 km due west and upstream) where the mean annual rainfall and daily temperature are 830 mm and 6.5 °C, respectively

During the 40 yr, 1933–1972, average ring widths declined linearly ($P<0.05$) and the deviations have been taken from the fitted line. Preliminary inspection of a segment of the data suggested that correlations with winter climate were very unlikely. Ring width deviations, therefore, were tested for correlations with rainfall amounts and mean temperature recorded over the full year and during the six summer months April–September, individually and in all possible combinations. Only three climatic parameters were significantly and independently related to ring width deviations (Table 1), two of which—annual temperature and the previous year's May–June rainfall—were linearly related, whereas the positive response per unit of May rainfall became less pronounced as the amount increased. These three terms are all significant when included in the following multiple regression, the multiple correlation coefficient for which is 0.67: $D = -2.8765 + (1.2339 \pm 0.3555)M^{0.1} + (0.1371 \pm 0.0485)T + (0.0012 \pm 0.0006)MJ$ where D is the ring width deviation (mm), M is May rain of the same year (mm; M 62.5, s.d. 30.4), T is annual temperature of the same year (°C; T 6.48, s.d. 0.55) and MJ is the total rain during May–June of the previous year (mm; MJ 113.1, s.d. 45.0).

Ring width deviations and these three climatic parameters were then subjected to spectral analysis followed by repeated curve fitting about the indicated harmonics. Three significant oscillations, and one just short of significant, were found in

Table 2 Climatic oscillations associated with the oscillations in ring width deviation shown in Fig. 1

	Period (yr)	Significance of fit	Amplitude ±	Mean	Lag between climate and ring width (yr)
Annual temperature	42.0	$P < 0.01$	0.34 °C	6.48 °C	None
May rain	23.0	$P < 0.01$	17.9 mm	62.5 mm	0.6
May rain	11.9	$P < 0.01$	21.0 mm	62.5 mm	None
June rain	4.44	$P < 0.05$	15.1 mm	50.9 mm	1 2

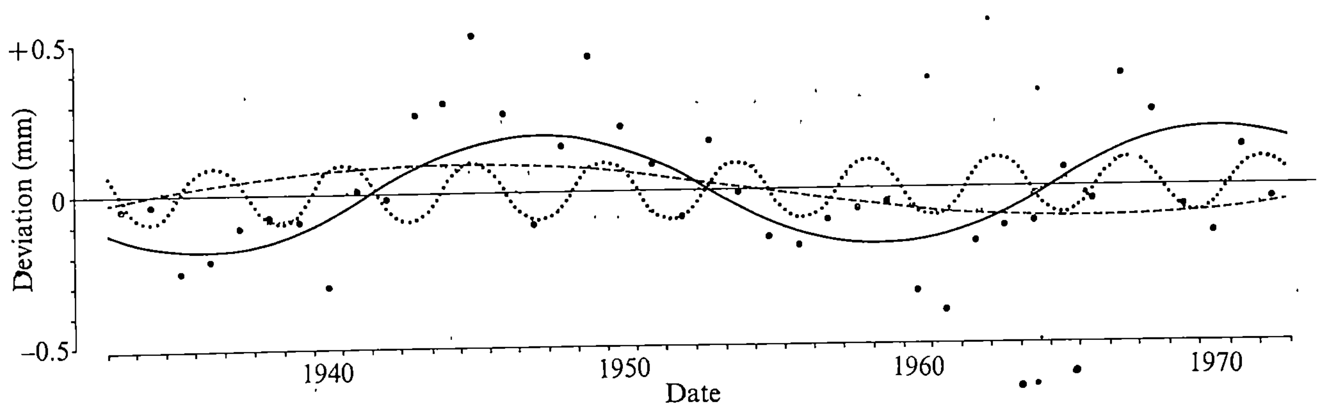

Fig. 1 Observed values of ring width deviation (●) and fitted oscillations; – – – – 42.0-yr period with amplitude 0.094 mm ($P < 0.05$), —— 23.0-yr period with amplitude 0.184 mm ($P < 0.001$), ·········· 4.44-yr period with amplitude 0.093 mm ($P < 0.05$) and a barely significant oscillation (fine dotted line) of 11.9 yr with amplitude 0.091 mm ($P < 0.1$).

Table 3 Occurrence of the four climatic oscillations associated with tree growth at Alltailleach forest at meteorological stations both to the west and east of the Grampian mountains

Station	Latitude	Longitude	Parameter and period (yr)			
			Annual temperature 42.0	May rain 23.0	May rain 11.9	June rain 4.44
Western

Braemar	57°00′N	03°24′W	NS	$P < 0.001$	$P < 0.05$	($P < 0.1$)
Balmoral	57°02′N	03°12′W	$P < 0.01$	$P < 0.01$	$P < 0.01$	$P < 0.05$
Aberdeen	57°08′N	02°08′W	$P < 0.05$	$P < 0.01$	$P < 0.001$	NS

the ring width deviations (Fig. 1); for each there was a matching oscillation in climate (Table 2) and there were no significant oscillations in these climatic parameters that were not reflected in the ring width deviations.

The absence of any previous mention of these relationships with tree growth in the British Isles, and the predominant influence of spring drought, promoted the idea that the climatic oscillations in Table 2 may be less pronounced, or may not occur, outside the rain shadow of the Grampian mountains. Accordingly the same climatic oscillations were looked for in three stations to the south and west and four stations to the north and east of the mountains (Table 3), the prevailing winds being southwesterly. The effect of the mountains on the oscillations in rainfall is quite striking, indeed the short term oscillation in June rain could only be detected at Balmoral and, less certainly, Braemar, two stations well up the Dee valley and tucked in behind the main mountain mass. These oscillations, therefore, may reflect variations in the strength of the westerlies. Further support for this suggestion can be found in a strikingly close similarity between the ring width pattern found at Alltcailleach and patterns published recently[10] for pine growing within the rain shadow of the Norwegian coastal mountains

Experimental interest in this tree stand was originally prompted by the belief of local Forestry Commission management staff that tree health and growth were declining severely It now seems that the decline from a peak positive deviation in 1945 to a large negative deviation in 1960 (Fig. 1) is primarily a reflection of the 23-yr cycle in May rain with the addition of the longer term temperature cycle. Irrespective of the experimental fertiliser application given in 1960, tree growth improved over much of the next decade but as the temperature was at the bottom of its cycle the optimum conditions of 1945 did not recur.

The number and length of these climatic cycles, coupled with the geographical variability in both their occurrence and their significance for tree growth, must counsel caution over recent attempts to explain patterns and trends of tree growth in terms of atmospheric pollution.

Energy expenditure in small children of obese and non-obese parents

Several recent studies have suggested the possibility of identifying some of the factors in infancy which contribute to the development of obesity in later life. For example, the abnormally rapid gain in weight of those infants who tend to become overweight later may be associated either with some genetic factor or with early overfeeding[1,2]. It is, however, highly probable that a child born to obese parents will itself become obese[3]. The main aim of this study was to see if it was possible to identify a difference in energy expenditure between children of 'normal' and 'obese' parents.

The energy intake and expenditure have been estimated in two groups of 4–5-yr-old children distinguished, not on the basis of their own weight, but according to the classification of their parents as being obese or non-obese. We found a difference which could be the result of either genetic or environmental factors. At this early age none of the children was significantly overweight for age or height, and the interest of this approach lies in the fact that any such differences observed may relate to factors contributing to obesity in later life.

Intake and expenditure measurements were made on 17 children and in a further three expenditure only was estimated. Height, weight and skinfold thickness were measured in all subjects. Body density was calculated from the regression equation of Brook[4] and body fat from the equation given by Siri[5]. Lean body mass (LBM) was obtained by subtracting the fat content from the total body weight. Apart from age and apparent good health, the main criterion of selection of subjects was the willingness of the parents and children to take part. The children were divided into two groups, those with one parent whose adult weight had at some time been more than 20% above desirable weight for height[6] (group O), and the remainder, neither of whose parents had ever been overweight (group N).

Daily energy expenditure was estimated from the integrated pulse rate for the day, based on the relationship between oxygen consumption and pulse rate. To establish this relationship, or to 'calibrate' the children, simultaneous measurements of oxygen consumption and heart rate were made on each child while he or she was lying down at rest and again while pedalling a stationary tricycle. Oxygen consumption was measured with a continuous air flow diaferometer, thereby eliminating the need for a face mask. Wherever possible more than two points on the calibration line were obtained. Integrated heart rate was then recorded on a SAMI (Socially Acceptable Monitoring Instrument) for 4 to 7 days and nights while the child went about his or her normal activities.

Energy intake was measured by analysing duplicate portions of all the food consumed by each child over a period of 5–7 d and the energy content of these portions estimated by ballistic bomb calorimetry[7]. The consumption of drinks was recorded separately and the energy content calculated from food tables[8,9].

Table 1 shows that although the two groups do not differ in body size, the estimates of energy intake and expenditure, including expenditure at rest, are significantly lower in group O than in group N. The degree of significance is greater when the results are expressed per kg body weight. The correlation coefficients of body weight, body fat and LBM with energy intake, expenditure and resting rate of expenditure have been calculated for all subjects. The only significant correlations are those of resting oxygen consumption with body weight (r +0.58) and LBM (r +0.64). The results show therefore that the resting oxygen consumption is affected by both body weight and by having one obese parent. Analysis of covariance shows that having an obese parent is highly significant over and above the effect of body weight, the latter tending if anything to mask the effect of the former.

The most critical questions arising from this study are whether the differences between the two groups result from metabolic or environmental factors or both, and whether these in turn are the result of genetic or acquired differences.

Energy is required for maintenance, physical activity and growth, the last accounting for only about 2% of the total expenditure[10]. The major portion is used for maintaining and resynthesising body tissue, to cover the heat increment of feeding and the minimum level of muscular activity needed for sustaining body functions. Energy expended while a subject is relaxed and inactive, as were the children in this study when they were at rest, would be expected to be similar to their maintenance requirement. The mean resting energy expenditure of all the children calculated on a 24 h basis was 1,110± 190 kcalorie.

The daily requirement of energy for maintenance has been estimated[10] to be ~ 105 kcalorie per kg$^{0.75}$ or 1.5 × basal metabolic rate. A similar figure was obtained by Spady[11] based on a study of energy balance in children recovering from malnutrition. For the children in this study 105 kcalorie per kg$^{0.75}$ averages 970 kcalorie. This is close to the average resting expenditure of the two groups (1,110 kcalorie). It seems reasonable, therefore, to take the difference between the observed total expenditure and resting expenditure as an estimate of the energy cost of voluntary physical activity. On this basis the energy expended on physical activity by the children in group O (190 kcalorie) was only half that expended by the children in group N (371 kcalorie).

It is of note that in a study carried out in the 1930s (ref. 12), the mean energy intake of 4–5-yr-old children was found to be 1,770 kcalorie. The maintenance requirement calculated according to the FAO/WHO estimate[10] would have been about 970 kcalorie, leaving 800 kcalorie available for physical activity —2–4 times that of the children in the present study. We know of

Table 1 Mean daily energy intake and expenditure

† Significant.
‡ Number in group N = 12; number in group O = 8 (except for intake study when it was 5).

no evidence to suggest that basal metabolic rates of children have fallen dramatically over this time, and the conclusion that the decrease in intake is associated with changes in patterns of behaviour seems inevitable. These, in turn, may reflect changes in the attitudes of parents towards expected levels of activity and play of children. Other aspects of living such as television and domestic heating standards may also be contributory.

We found a difference between the energy expenditure of children of normal and obese parents which is of the same order (350 kcalorie d^{-1}) as the decline in average intakes over the past 40 yr. Although this decline is likely to be due to environmental changes affecting voluntary activity levels, the children of obese parents also have lower resting rates of energy expenditure, and it will be of great importance in future studies to determine if this is the result of behavioural or of inborn metabolic differences.

Molecular evidence for dual origin of mangabeys among Old World monkeys

THE morphological similarities among the various mangabey species have been uniformly judged by primate systematists to warrant their association in a single genus (*Cercocebus*) of Old World monkeys. These similarities are not, however, reflected in their macromolecules. We find that the two groups of mangabeys are, by Old World monkey standards, so different at the protein level as to force the conclusion that the genus is not a natural, that is, monophyletic, group.

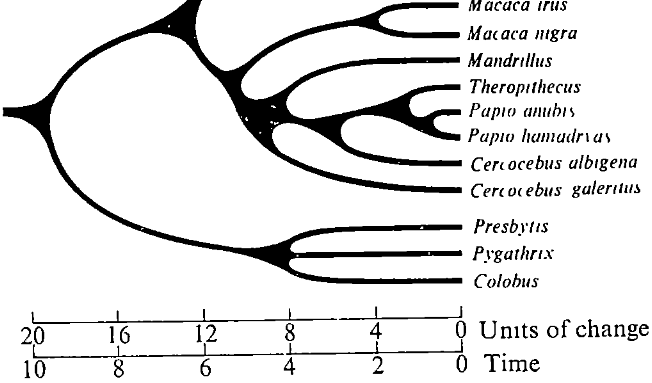
Molecular data have become an important, independent source of phylogenetic information. Though their application to specific problems in systematics has been limited, they have revealed a common origin for the New and Old World higher primates[1-3]; the monophyly of the pinnipeds among the arctoid carnivores (ref. 4 and paper presented at Society for Systematic Zoology meetings, 1975); the ursid nature of the giant panda[5,6], and the association of the tree frog *Hyla wrightorum* with *H. eximia* instead of *H. regilla*[7]. In each case, however, the problems were longstanding and the possible solutions available; the molecular data provided independent and objective ways of choosing among the possibilities. On the other hand, new sources of information can point out unsuspected situations, such as the strong probability that man is as closely related to the chimpanzee and gorilla as they are to each other (refs 1, 8–10 and an unpublished result).

The mangabey situation seems to be an example of this latter phenomenon, involving the probable misplacement of two species (*C. albigena* and *C. aterrimus*) among the Old World monkeys. We present here evidence that the two mangabey species groups—one containing *C. galeritus* and *C. torquatus* and the other *C. albigena* and *C. aterrimus*—may well be cladistically unrelated. We find our various sera representing the former species group (obtained as *C. fuliginosus* from the Davis Primate Center, and *C. galeritus* and *C. torquatus* from the Delta Primate Center) to be virtually indistinguishable both immunologically and electrophoretically. On the other hand, they are as distinct by these criteria from *C. albigena* and *C. aterrimus* as from any of the other 42-chromosome cercopithecine species (macaques and baboons). Finally, the *albigena–aterrimus* group seems to be an early offshoot of the baboon lineage, diverging from it some time after the separation of the *Mandrillus* (drill and mandrill) and *Macaca* lines and well before the *Papio–Theropithecus* radiation.

The Old World monkeys are divided into two subfamilies, Cercopithecinae and Colobinae, with the former containing the genera *Papio*, *Theropithecus*, *Cercocebus*, *Macaca* and *Cercopithecus*. These five contain some 35 species, and the strong evolutionary affinities among at least the first four are evidenced most strikingly by the ease with which viable intergeneric hybrids are produced[11,12]. With so complex a grouping of closely related forms and the absence of a detailed fossil record[13], we felt that a molecular study would prove useful in adding a new dimension to our systematic knowledge of the group, and the *albigena–aterrimus* finding is one striking result.

Antisera to numerous purified Old World monkey albumins and transferrins[14] were prepared in rabbits (Dutch belted, three or four per immunogen) according to published procedures[3,15] and pooled in reciprocal proportion to their microcomplement fixation (MC′F) titres. Differences among the various albumins and transferrins were measured using the MC′F procedure and are expressed as immunological distances[3]. Immunological distances are highly correlated with, and linearly proportional to, the number of amino acid sequence differences among the protein species being compared[16]. They are also additively apportionable along derived cladograms[2,3,17,18] and thus serve as reliable indicators of phylogenetic affinities among the taxa being compared. The data reported here were obtained using antisera to the albumins of *Papio cynocephalus*, *P. papio*, *Macaca irus*, *Cercopithecus*

Fig. 1 Albumin plus transferrin phylogeny of the Old World monkeys. This cladogram has been derived using procedures detailed in ref. 2. The complete data sets will appear in a comprehensive article on Old World monkey systematics. Immunological distances among the albumins and transferrins of the various species were obtained using the antisera listed in the text. The immunological distance separating any two forms was apportioned additively along the two lineages using antisera directed to the proteins of species outside the taxon involved. All such lineage pairs were then superimposed along common segments while minimising the differences among the experimental immunological distances and those derived from the cladogram.



aethiops and *Presbytis entellus*, and to the transferrins of *Theropithecus gelada*, *P. cynocephalus*, *P. papio*, *P. hamadryas*, *M. irus*, *M. nigra*, *M. speciosa*, *C. torquatus*, *C. patas*, *P. entellus* and *Colobus guereza*.

The detailed molecular systematics of the Old World monkeys will be presented elsewhere, but it is necessary to place the major lineages relative to one another before considering the position of the *albigena–aterrimus* group among them. The phylogeny is presented in Fig. 1 and its reliability can be assessed by comparing the immunological distances calculated from it and the experimental values. With each of the latter is associated an uncertainty deriving from non-reciprocity and experimental error, and these have appreciable significance given the very small distances involved in this study. The non-reciprocity of the input data matrix is ±1–2 units and the experimental error of each measurement is also between 1 and 2 units. Given this level of uncertainty or noise in the input data, the mean difference of 2 units between the elements of the input and output data half-matrices can only be taken to indicate that we would find essentially perfect additivity if we could deal with a set of data uncontaminated by immunological noise. But the observed noise level of 2 units should be remembered when assessing the reliability of the lineage placements in Fig. 1. We have attempted to indicate this visually by making the nodes areas rather than points. We then find the 42-chromosome Cercopithecinae (Papionini of Jolly[20,21]) forming a clade relative to *Cercopithecus*; within that clade *Theropithecus–Papio*, *Macaca*, *Mandrillus* and the *galeritus–torquatus* mangabeys form the major lineages.

The placement of the *albigena–aterrimus* lineage within this phylogenetic framework follows from a consideration of the data in Table 1 plus the albumin plus transferrin distances from *Papio* to: *Theropithecus*, 10 units; *Mandrillus*, 18; *Macaca*, 27; and *Cercopithecus*, 34. The distance between the two mangabey groups is 26 units, and the evolutionary significance of these observations is made evident when two colobines (*Presbytis* and *Colobus*) are used as reference species to assess the relative amounts of change in the two molecules along the lineages of interest. The colobine–*Papio* distance is 50 units; to the *galeritus–torquatus* mangabeys it is 51, and to the *albigena–aterrimus* mangabeys, 50. Thus in this case the albumins and transferrins have accumulated equal numbers of substitutions in the three lineages; therefore the fact that the two *albigena–aterrimus* molecules are more similar to their *Papio* counterparts than to those of the other mangabeys cannot be ascribed to a lack of change along either the *albigena–aterrimus* or *Papio* lineage. Thus we must conclude that the immunological data do not associate the two mangabey groups subsequent to the adaptive radiation of the Papionini and do indicate that the *albigena–aterrimus* lineage is probably an early offshoot of that leading to *Papio* and *Theropithecus*. This conclusion concerning the mangabeys is, of course, not the only interesting one from this study. The others will form subjects of future reports, but we note here the following. The various *Papio* species and *Theropithecus* are seen as very closely related at all levels surveyed here—albumin and transferrin immunology and plasma protein electrophoresis. Similarly the patas monkey, *Cercopithecus* (or *Erythrocebus*) *patas*, is found to be more closely related to the green monkey (*Cercopithecus aethiops*) than is any other *Cercopithecus* species. Finally the drill and mandrill (*Mandrillus*) form a lineage which is not specifically associated with *Papio–Theropithecus* (and, now, the *albigena–aterrimus* mangabeys).

In addition to the immunological studies just discussed, we have carried out some preliminary electrophoretic comparisons of the various sera used in this study. In the conditions used (7% acrylamide in a continuous 0.1 M Tris, 0.05 M glycine buffer), we typically see 20–25 serum protein bands staining with Coomassie blue. One can then use as a measure of similarity (*S*) between two samples simply the ratio of the number of bands with the same mobility in the two to the number of bands in the sample containing the smaller number.

Table 1 Albumin plus transferrin immunological distances between *Cercocebus* and other Old World monkeys

	C. galeritus	*C. albigena*
*C. galeritus**	0	26
C. albigena	26	0
T. gelada	25	16
Papio†	24	12
Mandrillus	16	12
Cercopithecus	20	30
Macaca‡	16	18
Colobinae§	51	50

*Antisera made to the albumin of a *C. galeritus* from the Delta Primate Center and to the transferrin of a *C. torquatus* from the Davis Primate Center fail to distinguish any of the various *galeritus–torquatus* individuals from each other

†Using antisera to the albumins of *P. papio* and *P. cynocephalus* and to the transferrins of *P. papio*, *P. cynocephalus*, *P. anubis*, *P. hamadrayas* and *P. ursinus*.

‡Using antisera to the albumin of *Macaca fascicularis* and to the transferrins of *M. fascicularis*, *M. nigra* and *M speciosa*.

§Using antisera to the albumin of *Presbytis entellus* and to the transferrins of *P. entellus* and *Colobus guereza*.

For intergeneric comparisons involving *Macaca*, *Papio*, *Cercocebus galeritus*, and *Mandrillus*, the observed *S* values are in the range 0.1–0.2. The *S* value between *P. cynocephalus* and each of the following is: *P. hamadryas*, 0.75; *T. gelada*, 0.6; and *C. albigena* or *aterrimus*, 0.35. Among the various *torquatus–galeritus* individuals in our collection, the *S* values are no less than 0.8; for the *albigena–aterrimus* comparison the value is 0.8; and between individuals in the two mangabey groups it is 0.15–0.2. Thus these preliminary electrophoretic data are consistent with the immunological picture.

Previous electrophoretic studies have detected marked differences in the mobilities of the α and β chains of *C. albigena* haemoglobin as compared with those of *C. galeritus*[21]. In addition, the peptide pattern of *C. albigena* haemoglobin is more like that of *Papio* than of *Macaca*[22]. This then completes a phylogenetic congruence among all the available molecular data relevant to mangabey systematics. We suggest that a DNA hybridisation study would provide useful additional information.

We emphasise that these conclusions concerning the positions of the two mangabey lineages should be regarded as suggestive working hypotheses to be tested in terms of the degrees to which they facilitate the interpretation of other bodies of comparative data bearing on cercopithecine evolution. One such test might begin with the observation that the mangabeys have sufficient morphological uniformity to have been placed consistently in a single genus—which is very significant in view of the tendency to splitting evident in Old World monkey taxonomy[11,23]. This morphological uniformity contrasts sharply with the molecular picture just presented. Such a contrast is no longer surprising in the context of the extensive recent documentation of the independence of rates of structural protein and organismal evolution[24–27], but its presence provides the opportunity to develop important insights into the evolution of the Cercopithecinae. If the contrast is real, then either mangabey morphology is primitive for the Papionini (baboons, macaques and mangabeys), or it is derived, in parallel or convergently, from the common ancestor of the group. This latter possibility is rendered unlikely by the fact that no one has yet seen mangabey morphology as derived[19,20,28,29]. Thus we are left with the former, leading to the important logical corollary that the larger derived Papionini—drill and mandrill, savanna baboons and gelada, and some large macaques such as *M. nigra* and *M. nemestrina*—simply represent slightly different ways of being a large Old World monkey starting from a mangabey-like morphological base.

One of the *albigena* samples (19354) was obtained from the Delta Regional Primate Center (DRPC) through Dr Charles Hill, and the other from eastern Zaire through Dr Urs Rahm. The two were immunologically indistinguishable. *C. aterrimus*

was provided by Dr Kurt Benirschke of the San Diego Zoo; *Papio* and *Theropithecus* by Dr J. Moor-Jankowski of LEMSIP; *Mandrillus*, *C. ascanius* and *C. guereza* by Dr William Mottram of San Francisco Zoo; *C. galeritus* (061-6979, 6984, 8512, 9093), *C. torquatus* (062-6992, 7004, 7191), *C. aethiops* and *C. patas* by DRPC; *C. torquatus* (CFU-2, 14, 26, 28) and *P. entellus* by Davis Regional Primate Center and *Macaca* by Dr Marjorie LaSalle of the Oregon Regional Primate Center. All work was done in the laboratory of Dr Allan C. Wilson of the University of California, Berkeley. We thank him for facilities and helpful discussion, together with S. L. Washburn and W. Malmi. Technical assistance was provided by Anne Hill and Peter Hornbeck and support through grants from the US National Science Foundation to A.C.W. and V.M.S. and a predoctoral fellowship to J.E.C.

Magnesium emitted by snails alters swimming behaviour of *Schistosoma mansoni* miracidia

Schistosoma mansoni is a parasitic flatworm transmitted by snails which infects millions of people in tropical countries with poor sanitation, where new irrigation schemes, population growth and continued poverty have increased the prevalence of infection. Larval worms, emerging from freshwater snails, penetrate human skin and mature in intestinal veins where they lay eggs. Many eggs remain in and damage tissues while others pass out in excreta and hatch in water, releasing embryos called miracidia These short lived, multicellular, ciliated, free-swimming miracidia must find, penetrate and reproduce within certain snails whence emerge the larvae infective for man. Snails emit substances ("miraxones") which alter the swimming behaviour of miracidia and may help them to locate and attack the snails[1-3]. Miracidial behaviour is reportedly affected by snail-elaborated amino acids[4,5] and by various other agents, including fatty acids[6,7]. We now report that magnesium appears in water in which uninfected *Biomphalaria glabrata* (a snail host of *Schistosoma mansoni*) is confined, and that magnesium ions alter miracidial swimming patterns.

Methods for rearing Puerto Rican (PR-2′) *B glabrata* and for obtaining miracidia from livers of mice infected with *S. mansoni* have been described before, as has a semi-quantitative bioassay for miraxone[1]. In this assay, miracidial responses are observed stereomicroscopically and scored 1 to 4+ after wells (1.5 cm diameter, each containing 50–100 miracidia in 0 3 ml of commercial spring water) are "point-inoculated" at the edge with 20 μl of test fluid; 4+ denotes strong, persistent miracidial aggregation and excitation around the zone of inoculation, whereas lower scores denote progressively less pronounced aggregations, as previously detailed[1]. Replicate experiments yielded similar results.

We have used the bioassay to detect miraxonal activity at each step of a procedure designed to isolate and purify miraxone(s) from "snail-conditioned water" (SCW) prepared by confining 100 snails (12–16 mm diameter) in 100 ml of food-free distilled water for 5 h at 24±1 °C. SCW was filtered through paper and successive batches were pooled and stored at −10 °C until processed. Lyophilising SCW yielded "snail-water powder" (SWP) which was extracted twice with chloroform–methanol, 2 : 1 (125 ml per g SWP) The pooled extract was shaken with distilled water[8], and the resulting lipid-free upper phase—containing most of the miraxone originally present in SWP—was separated, dried, dissolved in distilled water, and then passed through a Diaflo UM-05 ultrafiltration membrane (Amicon) retaining material of molecular weight >500. The filtrate was fractionated in Sephadex G-10 gel using distilled water as eluant, and a single band of miraxone was detected at V_e/V_0 (elution volume/void volume)=1.3–2.0. This miraxone was further purified by ascending paper chromatography in two successive solvent systems. (1) butanol–methanol–acetate–water, 4 : 8 : 1 : 1 (R_f, or migration relative to solvent front, of miraxone=0.5–0.8); and (2) isopropanol–pyridine–water, 7 : 7 : 2 (R_f of miraxone=0.3–0.55) A sample of 5 l of SCW yielded about 1 g SWP from which we obtained about 26 mg miraxone after the full purification process.

When eluted from the second paper chromatogram, the miraxone was soluble in water and alcohol; insoluble in ether, hexane and chloroform; heat stable (120 °C for 4 h); stable at all *p*H levels; strongly deliquescent; odourless, and non-volatile It formed a glassy film when dried. The product apparently lacked amino groups as it proved negative by ninhydrin spot tests and by fluorescamine analysis[9]. Tests for reducing sugars and fatty acids were negative. Mass spectroscopy to determine molecular weight failed because the material was non-volatile.

The purified miraxone contained 8.9–21.6% magnesium, 28.3–35.4% chlorine, 0–8.5% carbon, 5.8–6.0% hydrogen and 0 5–0.6% nitrogen (% by weight; range of two separately purified samples). Control experiments revealed that (1) distilled water, processed through the purification scheme described above, yielded no miracidial stimulant and only 0.03% of the magnesium present in SCW-purified miraxone, and (2) the carbon and nitrogen in miraxone probably represented contaminants from chromatography.

A grey residue, remaining after purified miraxone was ashed, contained 28% magnesium by weight but only traces of other metals When this ash was dissolved in 0.5 N HCl, dried, and dissolved in water, its miraxonal activity (as measured at serial twofold dilutions[1]) resembled that of the miraxone before ashing. By contrast, when SWP was ashed and dissolved as described, its activity decreased, perhaps

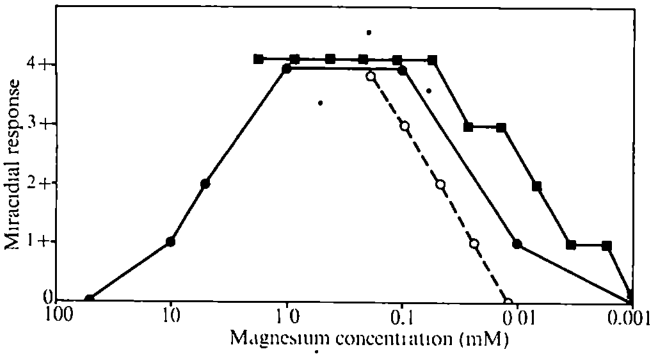

Fig. 1 Responses (1 to 4+) of *S. mansoni* miracidia, plotted against magnesium concentrations in serial dilutions of: commercial magnesium chloride (●); a typical sample of *B. glabrata*-conditioned water (○), and miraxone purified from *B. glabrata*-conditioned water as described (■). Dilutions were all made with distilled water. Magnesium concentrations were determined by atomic absorption spectrophotometry The decreased miracidial response at concentrations of commercial magnesium chloride above 1 mM represents an unexplained effect also observed with some highly concentrated preparations of miraxone. Tests with magnesium sulphate yielded curves resembling that shown for magnesium chloride.

because ashing may alter the ratio of magnesium to interfering cations (see below).

The purified miraxone migrated 9–12 cm cathodally in high voltage paper electrophoresis (30 min at 3 kV; buffer, pyridine-acetate-water, 400 : 16 : 3584; *p*H 6.42; Whatman 3MM paper); therefore, the miraxone is a cation at this *p*H. Electrophoresis removed chloride from the miraxone but left the biological activity unchanged.

The above findings suggested that the material purified from SCW is magnesium chloride, and that the biologically active miraxone is magnesium ion. This hypothesis is strengthened by three other lines of evidence First, aqueous solutions of $MgCl_2$ or $MgSO_4$ (1.0–0.1 mM) evoked strong miracidial responses (Fig. 1), while solutions of $CaCl_2$, KCl, K_2SO_4 and NaCl (1.0–0.001 mM) elicited no miracidial response. Second, when we processed magnesium chloride ($MgCl_2.6H_2O$, ACS grade, Fisher Scientific) through the purification scheme (starting with chloroform–methanol extraction), miraxonal activity purified exactly as the SCW-derived miraxone at each step. Finally, $MgCl_2.6H_2O$ contains, by calculated weight, 12% magnesium, 35% chlorine and 5.9% hydrogen—values close to those of the purified miraxone.

Several additional findings favour magnesium ion as the major miraxone in SCW. Fresh SCW, which induces 4+ miracidial responses, contained an average of 0.24 mM magnesium (range: 0.17–0.35 mM). More important, the dilution–response curves for SCW and for purified miraxone parallel that of magnesium chloride at comparable magnesium concentrations (Fig. 1). The magnesium content of SCW, therefore, can account for the miraxonal activity of this solution assuming that all or most of the magnesium is chemically 'available' as a miracidial stimulant and that other components of SCW do not interfere with miracidial stimulation by magnesium.

To test for other miraxones in SCW, the magnesium concentration in test wells containing miracidia was made up to 0 33 mM by adding $MgCl_2.6H_2O$ 5 min before challenging the miracidia with SCW of known activity. Although the miracidia swam normally, they did not respond to the SCW. This result is consistent with magnesium being the only major miraxone in SCW. The increased background magnesium (now greater than that of SCW) would have eliminated any magnesium gradient from the inoculated SCW, but this should not have affected gradients of other miraxones if any such were present. We cannot, however, deny that magnesium could nonspecifically inhibit miracidial responses to other hypothetical miraxones.

The miraxonal activity of a solution may depend in part on the concentrations of inorganic ions other than magnesium. For example, the activity of SCW[1] and of a 0.47 mM magnesium chloride solution is reduced if 34 mM NaCl is added to these solutions before bioassay. Although we do not understand the basis for this effect, the blockage suggests that direct comparison of the miraxonal activity of purified and crude materials may be misleading because interfering ions or other substances may be present in the crude preparations.

Although we do not exclude the possibility that organic molecules in crude SCW contribute to some of its miraxonal activity, our findings show that magnesium ion accounts for most of that activity. Since previous evidence indicates some nonspecificity between the snail species releasing miraxone(s) and the species of miracidium responding[1–3], perhaps the miracidia of many species of trematode respond to magnesium. This response may be a requisite part of the miracidial host-finding process. It remains to be shown how snails release magnesium, how miracidial behaviour is altered by magnesium and how this information can be used to interrupt the transmission of schistosomiasis.

We acknowledge preliminary research by Dr Robert Murphy, and the technical assistance of Ms Christine A. Burns and Ms Nora S Anderson. This study was supported in part by a research grant, and by a research career award to E C, from the US Public Health Service.

Temperature dependence of biochemical oscillations in cell suspensions of *Dictyostelium discoideum*

ON a substratum the aggregation of amoebae of *Dictyostelium discoideum* often occurs in pulses because the aggregation centres release the chemotactic signal periodically[1,2]. The signal is believed to be cyclic AMP[3,4]. Cyclic AMP oscillations have been observed in suspensions of aggregation competent cells of *D. discoideum*[5]. Since circadian rhythms are largely compensated for temperature effects[6] the temperature dependence of other biological rhythms is of general interest.

In suspensions of *D. discoideum* cells, changes in absorbance accompanying periodic cyclic AMP production can be recorded[5,7]. These changes occur as an initial series of spikes followed by sinusoidal oscillations[7]. We have studied the sinusoidal oscillations since they were found to

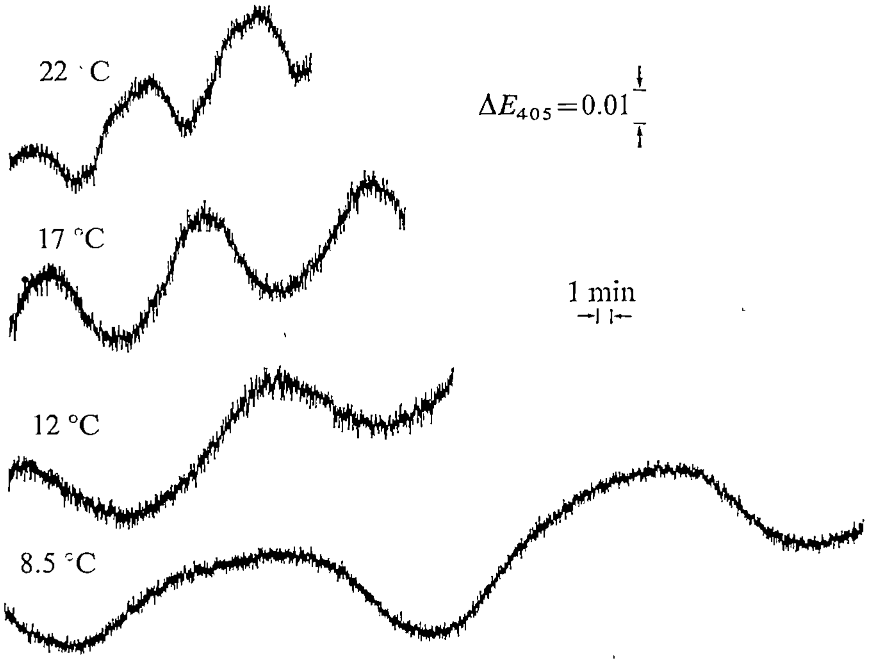

Fig. 1 Oscillations in cell suspensions of *D. discoideum* at different temperatures. Amoebae of the axenic strain Ax-2 (clone 214) were cultivated at 23 °C on nutrient medium supplemented with 1.8% maltose[11] and collected at cell densities of 0.2 to 1×10^7 ml^{-1}. The cells were washed three times in the cold with 0.017 M Soerensen phosphate buffer, *p*H 6.0, adjusted to 1×10^7 cells ml^{-1} in buffer and shaken for 4 h at 23 °C. After this the amoebae were centrifuged, adjusted to 5×10^7 cells ml^{-1} in buffer, transferred into a cuvette with an optical path of 1 cm, and agitated by bubbling oxygen at a flow rate of 24 ml min^{-1} through the suspension. With a Zeiss PM6 spectrophotometer the optical density at 405 nm was recorded. Changes in absorbance seem to be due to changes in light scattering[7] and indicate changes in shape or size of cells. The absorbance decreases towards the top. The starting temperature was 22 °C and after sinusoidal oscillations began (after ~ 1 – 2 h) the temperature was either kept at 22 °C or slowly shifted to 17 °C, 12 °C, or 8.5 °C. In all experiments the actual temperature in the cuvette was determined

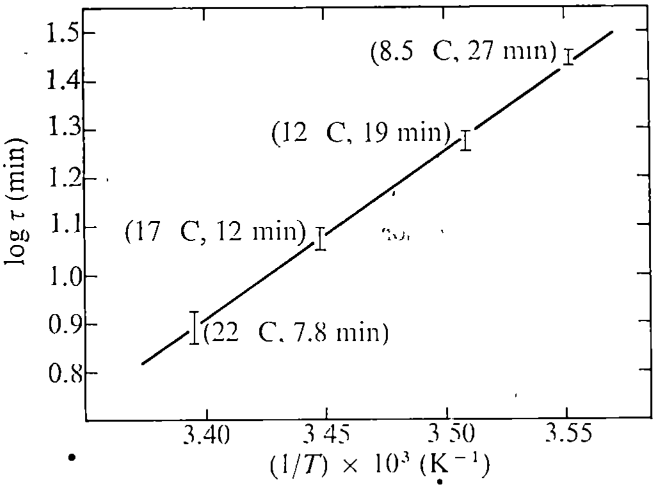
proceed for more periods than the spikes. Sinusoidal oscillations of amoebae of *D. discoideum* strain Ax-2 (clone 214) have been observed in the temperature range from 7 °C to 24 °C. As shown in Fig. 1, by decreasing the temperature from 22 °C to 8.5 °C the oscillation period increases from 7.8 to 27 min. The dependence of the oscillation period τ on the temperature T can be described by the Arrhenius equation (Fig. 2), and an activation energy for the oscillating system of $E=16$ kcalorie is obtained.

Temperature does not affect the form of sinusoidal oscillations (Fig. 1). At any temperature the part of the wave from the maximum to the minimum in absorbance is longer than that from the minimum to the maximum. The amplitude does not decrease with decreasing temperature, on the contrary, in some experiments higher amplitudes were obtained at lower temperature.

Fig. 2 Dependence of the oscillation period on the temperature. The Arrhenius equation was applied in the form

$$\log \tau = (E/2.3RT)+\text{constant}$$

(where τ is the oscillation period, R the gas constant, and T the absolute temperature) and $\log \tau$ was plotted against T^{-1}. The Celsius temperature and the period of oscillation are given in parentheses. At 22 °C sinusoidal oscillations of Ax-2 amoebae in suspension ceased after about 20 periods, and the period length decreased from the beginning to the end by 10 to 20%. At each temperature the period length was determined between 5 and 10 oscillation periods from the beginning. The data represent the range of period lengths evaluated from at least 4 oscillation periods at each temperature



During the course of these studies we learned from Nanjundiah that he and his colleagues[8] have investigated the temperature dependence of the frequency of periodic movement steps during the aggregation of amoebae of *D. discoideum* strain NC-4H on agar. Although at any temperature the oscillation period of NC-4H amoebae on agar is shorter than that of Ax-2 amoebae in suspension, the activation energy is the same under both conditions: 15.8 kcalorie (ref. 8) compared with 16 kcalorie. This result is in accord with the assumption that the same biochemical oscillator underlies rhythmic signalling of aggregation centres on agar as well as periodic activities in cell suspensions.

Nanjundiah *et al.*[8] interpreted E as the activation energy of a rate-limiting step in the biochemical oscillation. Alternatively a linear Arrhenius plot for a network of reactions results if the activation energies of all individual steps are similar. The activation energy of 16 kcalorie is in the range of those calculated for enzyme-catalysed reactions[9]. A nonenzymatic chemical oscillator, the Belousov–Zhabotinskii system, shows an even stronger temperature dependence of the oscillation period[10], corresponding to an activation energy of 26 kcalorie (as calculated from the data of ref. 10).

I thank Drs G. Gerisch, F. Grun and V. Nanjundiah for stimulating discussions. This work was supported by the Schweizerische Nationalfonds.

Effect of temperature on morphogenetic oscillations in *Dictyostelium discoideum*

WHEN their food supply is exhausted, single amoebae of the cellular slime mould *Dictyostelium discoideum* aggregate[1]. On a two-dimensional substrate such as agar, this aggregation is the result of a succession of periodic coordinated movement steps directed towards a group of amoebae—the "centre", which may in fact lie anywhere in the field of cells Recent theoretical[2,3] and experimental[4-7] work suggests that this process can be explained as follows (1) The centre produces and releases cyclic AMP (the signal) in an oscillatory manner, and (2) other cells in the field respond chemotactically by moving up cyclic AMP gradients and relay the signal progressively outwards. By means of time-lapse cinematography we have looked at the oscillation frequency ν during the aggregation of small drops (about 1,000 cells in a drop of diameter 1 mm) of *D. discoideum* cells (strain NC-4H) aggregating on hydrophobic agar[8] at various temperatures, and have found that the oscillation frequency increases with temperature (Fig. 1).

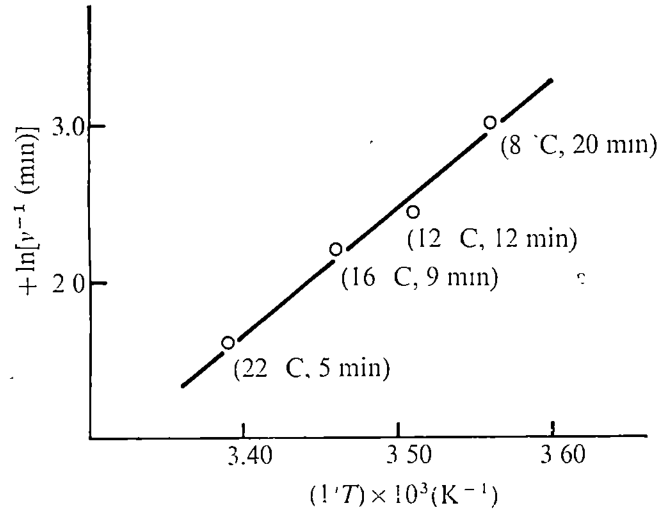

Fig. 1 T is the absolute temperature and ν the frequency of oscillation. Experimental points are fitted to the curve $\ln(\nu^{-1}) = \ln(\nu_0^{-1}) + (\Delta E/R)T^{-1}$, with R equal to the gas constant. Figures in parentheses indicate the temperature (°C) and period of oscillation. The amoebae were deposited in a drop of Bonner's salt solution[11] on agar, and the agar plate was kept in the temperature-controlled room for 2–3 h before aggregation began. Temperature varied within ±0.5 °C of the recorded means. Periods were recorded as differences in times of initiation of wave propagation at the centre, each such initiation having the appearance of a quick contraction. Mean frequencies were estimated from two experiments at each temperature with about 15 oscillations recorded during each aggregation A sample run of periods, recorded at 12 °C, reads 13, 12, 12, 13, 13, 12, 12, 12, 11, 12 min. The aggregates were concentric, that is, morphologically similar in all experiments

These amoebae aggregate and form viable spores (as tested at 22 °C) down to 8 °C. The Arrhenius plot ($\ln\nu^{-1}$ against $\ln T^{-1}$) is linear, corresponding to a frequency factor $\nu_0 = 2\times10^9\ \mathrm{s}^{-1}$ and an activation energy $\Delta E = 15.8$ kcalorie mol^{-1}. ΔE can be interpreted as the activation energy of a (hypothetical) rate-limiting step in the overall scheme for the biochemical oscillation. It is noteworthy that this value of ΔE is in the range of activation energies for non-transport enzyme-catalysed reactions[9], whereas those for known specific transport processes are much smaller[10]. In parallel with the increase in oscillation frequency, there is also an increase in the mean speed of amoeboid movement (not shown) Thus, other factors being the same, the number of pulses needed for a field of cells to aggregate ought to be only weakly temperature dependent. In fact, if we consider just those cases (four in all) where oscillations could still be observed till late in aggregation, this number was 20 at 12 °C, 19 at 16 °C and 17 at 22 °C. Rigorous substantiation of this last result would suggest that there is an underlying oscillator controlling movement, possibly coupled to the one involved in signal generation.

External cyclic AMP-dependent protein kinase activity in rat C-6 glioma cells

IN certain eukaryotic cells β-agonistic catecholamines bind to membrane-associated hormone receptors, and stimulate the intracellular synthesis of cyclic AMP by activation of the adenylate cyclase[1] In C-6 rat glioma cells stimulated with noradrenaline this increase of cyclic AMP leads to, or is correlated with, a morphological change in the cells[2]. When the intracellular cyclic AMP concentration has reached a maximum, it returns to basal values[2] due to an energy-dependent excretion of cyclic AMP from the cell into the external medium[3,4], similar to that found in several mammalian systems[5-7]. It is possible that the excreted cyclic AMP interacts either with an external, glial-membrane bound cyclic AMP receptor or with the surface of the surrounding cells, for example neurones. We report here that intact, cultured glial cells seem to have a cyclic AMP-dependent protein kinase on their external surface which transfers γ-phosphate of ATP to an external acceptor protein (histone). This protein kinase activity is stimulated indirectly by the addition of noradrenaline to the cells The physiological significance of this process is unknown

We first tested the effect of extracellular cyclic AMP on the ability of a protein kinase activity of intact C-6 cells to phosphorylate an exogenous substrate. Figure 1 shows the phosphorylation by C-6 cells of added external histones as a response to incubation in the presence of 5×10^{-6} M cyclic AMP. These data suggest that actively growing glial cells have a cyclic AMP-dependent protein kinase, probably on the external cell surface, which can be stimulated from the outside of the membrane The same experiment showed that a small fraction of ^{32}P radioactivity remained with the cells and that there was no significant difference between stimulated and unstimulated cells with respect to this accumulation (data not shown).

There are two possible objections to the experiment

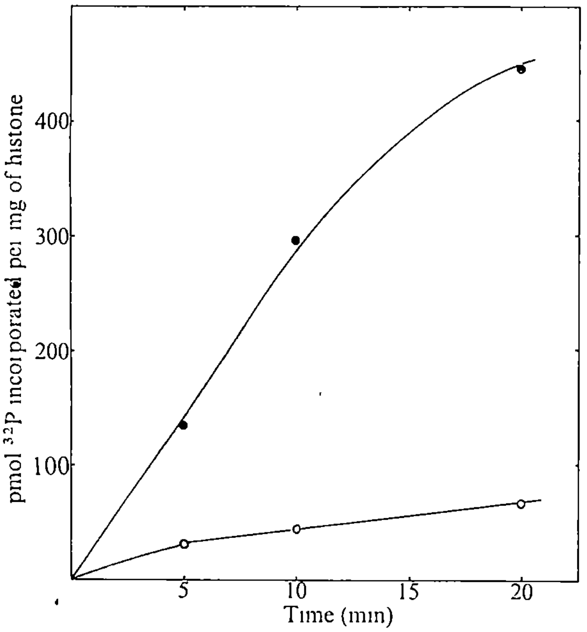

Fig. 1 Activation of external protein kinase-mediated incorporation of ^{32}P into histone. C-6 rat glioma cells (flow laboratories), originally derived by Benda *et al.*[9], were grown routinely in 60-mm Petri dishes with Ham's F-10 medium supplemented with 15% horse serum, 2.5% foetal bovine serum and gentamicin (50 μg ml^{-1}) in an atmosphere of 90% air and 10% CO$_2$ at 37° C. All experiments were performed with confluent cultures (about $3-4\times10^6$ cells per plate) since it has been shown that cell–cell contact is required for maximal increase of internal cyclic AMP after hormone treatment[10]. To measure the external protein kinase activity, the cells were first washed three times with prewarmed Dulbecco's phosphate-buffered saline (PBS), then 1 ml of reaction buffer (50 mM MOPS buffer, *p*H 7.2, 5 mM MgCl$_2$, 0.125 mM CaCl$_2$, 125 mM sucrose, 7 mM mercaptoethanol) was added to start the incubation. The reaction buffer included γ-^{32}P-ATP (specific activity 1.3×10^3 c.p.m. pmol^{-1}), prepared according to Glynn and Chappel[11], and calf thymus histones (300 μg ml^{-1}, Calbiochem). If the effect of cyclic AMP was to be measured, the reaction buffer also contained 5×10^{-6} M cyclic AMP. During the experiment the dishes were placed on a constantly moving, shaking table. After the periods indicated at 35° C, the buffer was removed and the cells were washed with 1 ml of cold PBS. Buffer and washings were combined and centrifuged (2 min, 1,500*g*), and protein in the supernatant was precipitated with 10% trichloroacetic acid (TCA). The precipitates were collected on Whatman GF/A glass fibre filters. The filters were washed six times with 5 ml of 5% TCA and once with 3 ml of methanol, dried and counted in a liquid scintillation counter. The cells were washed three times with cold PBS and lysed with 1 ml of 0.1% sodium dodecyl sulphate. The cell lysates (1 ml) were counted in 10 ml of a toluol–Triton X-100 mixture (9 parts toluol+1 part Triton X-100 containing 0.5% PPO). Each point represents the mean of three determinations: ●, 5×10^{-6} M cyclic AMP; ○, without cyclic AMP.

shown in Fig. 1. Perhaps the cyclic AMP added to the culture medium penetrates into the cells and activates an internal protein kinase. This is unlikely because it seems improbable that cyclic AMP enters glioma cells—it does not induce the characteristic morphological alterations which are a prompt response of these cells to the addition of dibutyryl cyclic AMP or catecholamines (our unpublished observations). It is also possible that a small fraction of the cells disintegrate during incubation. Cytoplasmic cyclic AMP-dependent protein kinase could then phosphorylate the added histones. This possibility is also unlikely because microscopy has revealed no gross alteration of cellular integrity. Contamination is ruled out by the experiments summarised in Table 1. These controls show that less than 2% cyclic AMP-dependent protein kinase activity was found in the incubation buffer after contact with the cells. The time course shown in Fig. 1 also excludes the possibility of contamination. The external protein kinase is most active at cyclic AMP concentrations higher than 10^{-8} M and has a *p*H optimum of about 7.2 (data not shown).

Table 1 Control experiments

	pmol ^{32}P incorporated per mg of histone per 10 min	
	Reaction buffer without cyclic AMP	Reaction buffer with 5×10^{-6} M cyclic AMP
Cell-free supernatant	5.05±0.85	5.25±0.44
Standard reaction procedure (with cells)	38.42±2.24	302.56±4.37

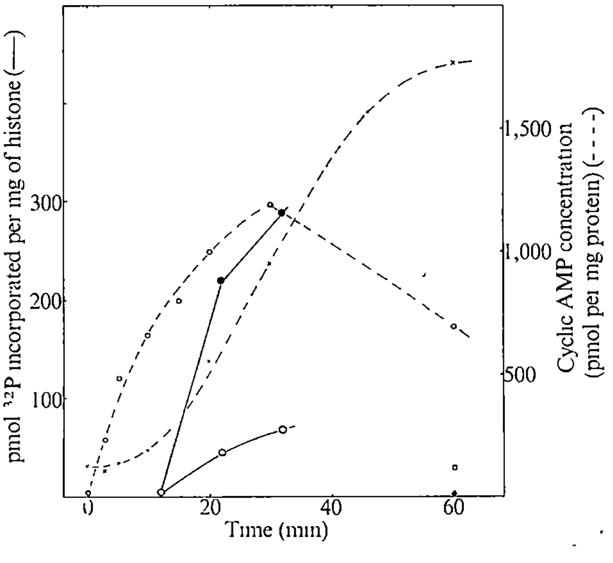
Each value represents the mean ±s.e. of five determinations.

To show that the external protein kinase activity is really located at the cell surface we added the ^{32}P acceptor protein to the reaction buffer after having incubated the buffer with growing cells. Incubation buffer without histones was removed from the cells after 10 min of incubation at 35° C in the conditions described for Fig. 1. The sample was centrifuged for 5 min at 1,500*g* and protein kinase activity in the cell-free supernatant was determined after addition of histones. The radioactivity in TCA-precipitated histones was determined after 10 min of incubation as described for Fig. 1 (cell-free supernatant). These values are compared with values obtained when histones were present with the cells during the first 10-min incubation and the second incubation not performed (standard reaction procedure).

Secretion of cyclic AMP from C-6 rat glioma cells into the medium was originally described as a response to treatment with L-isoproterenol[3,4]. We show here that noradrenaline also causes secretion of cyclic AMP from glioma cells.

Figure 2 shows the intracellular and extracellular levels

Fig. 2 Activation of external protein kinase by noradrenaline. Noradrenaline (10^{-4} M, Sigma) was added to confluent C-6 glioma cells growing in 60-mm dishes with 1 ml of medium. At the times indicated, cyclic AMP was extracted with 5% TCA as described by Oey[2] and cyclic AMP concentration was determined according to Gilman[13]. For protein determination[12], bovine serum albumin (Sigma) was used as standard. To measure the ability to transfer ^{32}P into histone in the presence of noradrenaline the cells were preincubated in Ham's F-10 medium for 12 min. Then the medium was replaced with incubation buffer containing 10^{-4} M noradrenaline and the protein kinase activity was measured as described for Fig. 1. Each value represents the mean of duplicate determinations on two cell populations. —●—, Protein kinase activity in the presence of noradrenaline; —○—, in the absence of noradrenaline; - - ○ - -, internal cyclic AMP concentration in the presence of noradrenaline, ×, external cyclic AMP concentration with noradrenaline; △, internal cyclic AMP concentration without noradrenaline; □, external cyclic AMP concentration without noradrenaline. The cyclic AMP efflux from growing C-6 cells into incubation buffer occurs at nearly the same rate as into medium (data not shown).



of cyclic AMP after incubation in the presence of 10^{-4} M noradrenaline. After a short lag period, cyclic AMP appeared in the external medium The external protein kinase could also be activated by treatment of the cells with noradrenaline. This is most clearly demonstrated by the experiments shown in Fig 2.

The best known and probably the main receptor for cyclic AMP in eukaryotic cells is the regulatory subunit of a protein kinase After binding cyclic AMP, the regulatory subunit is released from the catalytic subunit, thereby stimulating the activity of the enzyme[8].

We thank Professor R. Knippers and Drs T Lindl and A Powling for helpful discussions. This work was supported by a grant from the Deutsche Forschungsgemeinschaft.

H–2 region product as determinant in immune cytolysis of syngeneic tumour cells by anti-MSV T lymphocytes

THE existence of cytolytic T lymphocytes (CTL) specific for antigenically related tumour cells during oncornavirus-induced oncogenesis in the primary host is well documented. They exist in murine sarcoma virus (MSV) tumour-bearing mice, during and after the tumour rejection[1], and in Friend virus-infected mice, notably in the spleen of resistant C57BL/6 (ref. 2) It is probable that they play some role in tumour cell destruction *in vivo*[3] and it can be supposed that the antigens of the tumour cell surface recognised by CTL are at least, for the most part, viral proteins or glycoproteins. It was suggested that CTL reacting with virus producer cells in non-oncogenic systems[4], or with hapten-modified cells[5,6] recognise an H–2-modified antigen. Therefore, it was of interest to determine whether the same situation exists in an oncornavirus tumour system. It is already known that anti-MSV CTL are much more efficient against syngeneic than against allogeneic tumour cells[7,8], indicating that H–2 antigens may play some role in the CTL–target cell interaction. We report here that the H–2 specificities of the tumour cell surface determine the interaction with syngeneic anti-MSV CTL, the reacting antigen being either an H–2 specificity modified by the virus, or, less probably, a virus-induced antigen modified by an *H–2* region product.

Anti-MSV CTL derived from different inbred lines and their F_1 hybrids or congenic partners were tested against tumour cells of various H–2 specificities. CTL were taken from the spleen 10–16 d after virus inoculation in BALB/c (*H–2*^{d}), B10.D2 (*H–2*^{d}), BALB B (*H–2*^{b}), C57BL/6 (*H–2*^{b}) and (BALB/c×C57BL/6)F_1 (*H–2*$^{b/d}$). All mice were from our colony except BALB.B (Dr F. Lilly, Albert Enstein College, Bronx, New York) BALB/c (C) and BALB.B differ only at the *H–2* region of group linkage IX (chromosome 17). A similar situation exists between C57BL/6 (B6) and B10.D2, the latter being congenic to C57BL/10, closely related to B6. Tumour cells were YC8 and LSTRA in C, and MBL2 and FBL3 in B6 YC8, LSTRA and MBL2 were Moloney virus-induced lymphomas; whereas FBL3 was induced by Friend virus. All of them are FMRGi(+) cells as defined serologically. MBL2 and FBL3 reacted similarly with B6 anti-MSV CTL as do LSTRA and YC8 with C anti-MSV CTL. The CTL activity was tested using the chromium release test (CRT) carried out at 100 : 1 CTL–target cells ratio with an incubation period of 6–16 h as described previously[1]. It was demonstrated earlier that in the MSV system the cytolytic activity is entirely due to T cells[1,9]. Results (Table 1) show that B6 anti-MSV CTL are strongly cytolytic for B6 and only weakly for C targets, the reverse situation being observed with C anti-MSV CTL. (B6×C)F_1 CTL which possess both *H–2*^{d} and *H–2*^{b} determinants of their parental strains are fully effective against *H–2*^{d} and *H–2*^{b} targets CTL obtained from congenic lines behave exactly like their H–2 identical partner: BALB.B CTL lyse B6 better than C tumour cells, whereas B10/D2 are mainly effective against C cells The use of congenic lines is particularly demonstrative of the H–2 participation in CTL-induced cytolysis since they differ from their congenic partners only by the *H–2* region. In experiment 1 a weak CTL activity exists for allogeneic targets, also found occasionally in other unpublished experiments. An H–2 incompatibility does not therefore completely abolish the CTL reaction, but as a rule the allogeneic reaction remains very weak as shown in quantitative experiments (F. Plata *et al*, unpublished) One can therefore conclude that H–2 specificities are determinant in the reaction, H–2 compatibility between CTL and the target being necessary for a fully efficient immune cytolysis. Two hypotheses can be proposed to explain this phenomenon. (1) CTL recognise MSV antigens by a specific determinant, but they need at the same time an identical H–2 on their surface and on the target cell to become fully cytolytic. In other words two different structures are involved separately on the tumour cell: H–2 antigens and the MSV specificities, (2) anti-MSV CTL recognise on the tumour cell surface only one structure which is either an H–2 antigen modified by a viral product, or a viral antigen modified by an H–2 region product. According to the first hypothesis, CTL from F_1 hybrids bearing the H–2 specificities of their two parental lines, F_1 immune CTL must react with any parental cells possessing the MSV-induced antigens. On the contrary, if the second hypothesis were correct, F_1 CTL would react only with target cells sharing an identical H–2 with the immunising parental tumour cells.

Table 1 Specific chromium release (%) by MBL2 (B6) and LSTRA (C) tumour cells attacked by anti-MSV CTL from different strains

Anti-MSV spleen cells from:	Target cells MBL2 Expt 1	MBL2 Expt 2	LSTRA Expt 1	LSTRA Expt 2
BALB/c (C)	7	0	17	34
C57BL/6 (B6)	34	26	7	0
(C×B6) F_1	39	—	16	—
BALB B	45	—	8	—
B10.D2	7	—	24	—

(C×B6)F_1 were therefore immunised either by MSV inoculation (which induces F_1 transformed cells *in vivo*) or by 10^5 MBL 2 or FBL 3(B6) or LSTRA (C) tumour cells given subcutaneously. CTL were taken from the spleen about 2 weeks later and tested using the CRT against B6 and C targets Results show (Table 2) that hybrids immunised against the virus produce CTL reacting with both MBL2 and YC8. On the contrary, hybrids immunised against C or B6 tumour cells produce CTL which react only

Table 2 Cytolytic activity of (C×B6)F$_1$ CTL for B6 and C tumour cells (% specific chromium release)

Immunisation by:	Target cells MBL2 (B6)	 YC8 (C)	 LSTRA (C)
MSV inoculation	38	—	16
	13	8	—
	36	21	—

	4	—	26
	0	—	12
MBL2 (B6) tumour cells	7	0	—
FBL3 (B6) tumour cells	13	0	—
	12	0	—

with the immunising cells or antigenically related cells of the same line. One can conclude that H–2 compatibility between CTL and the target is not enough to permit immune cytolysis. Hybrids (*H–2*$^{b/d}$) which received the virus and developed MSV tumour cells have been immunised with MSV antigens associated with (or modified by) H–2^{b} and H–2^{d} on the tumour cell surface. Therefore, they react with YC8 (*H–2*^{d}) as well as MBL2 (*H–2*^{d}) lymphoma cells. On the other hand, hybrids which received parental tumour cells have been immunised only against tumour antigens associated with the H–2 specificity of the immunising line, and do not therefore react with the tumour antigen of the other parental line. At this stage in the experiments it seems highly probable that anti-MSV CTL recognise only one structure on the target cell surface—an antigen which is different according to the H–2 of the host.

This structure could be an H–2-modified antigen due to the interaction of viral proteins or glycoproteins with H–2 molecules on the tumour cell surface, as proposed for non-oncogenic virus systems[4] and Hapten-modified cells[5,6]. According to this hypothesis H–2 and MSV antigens must be closely associated and a preincubation of the targets with related H–2 antibodies ought to block the activity of anti-MSV CTL. Another possibility would be that the virus-induced antigens could be modified by a product of the H–2 region, as proposed in experiments using CTL directed against non-H–2 specificities on the normal cell surface[10] In this case H–2 and MSV antigens are not necessarily associated on the tumour cell surface, and anti-H–2 antibodies would not necessarily block activity. To demonstrate a close topographical relationship between H–2 and MSV antigens, C anti-B6 and B6 anti-C antisera prepared by repeated inoculations of normal spleen cells. These sera were used either unabsorbed or after absorption *in vivo* on congenic spleen cells to provide H–2 and non-H–2 typing sera. For example, C anti-B6 absorbed on BALB.B provides a 'non-H–2 typing serum', whereas the same sera absorbed on B10/D2 provides an 'H–2 typing serum'. Target cells (2×10^{4}) were incubated for 30 min at 4 °C in 0.2 ml 1/10 diluted typing serum, then used in the CRT as above. Controls were incubated either with normal mouse serum or with unrelated anti-H–2 typing serum. Results (Table 3) show that unabsorbed and anti-H–2 typing sera block the activity of anti-MSV CTL, whereas non-H–2 typing sera are devoid of blocking activity. Furthermore, a BALB/c anti-BALB.B typing serum which reacts only with H–2 is fully blocking. Anti-Thy1–2 (AKR anti-C3H/He) incubated with the Thy1–2(+) MBL2 lymphoma cells did not inhibit their cytolysis by anti-MSV CTL. In addition, unrelated anti-H–2 (for example, B6 anti-C on B6 cells attacked by B6 anti-MSV CTL) are not blocking. It is clear therefore that anti-H–2 have a definite and specific blocking activity for anti-MSV CTL. This result indicates a close topographical relationship between H–2 and MSV antigens and favours the hypothesis of an H–2-modified specificity at the surface of oncornavirus-infected cells. One cannot definitely rule out the hypothesis, however, of a steric hindrance by anti-H–2 antibodies, due to the proximity of H–2 and MSV antigens, without structural relationship between them. Note also that repeated washings of the target cells after incubation with anti-H–2 clearly altered their blocking activity. It is therefore not possible to draw a definite conclusion from these experiments.

H–2 specificities are clearly determinants in the interaction of anti-MSV CTL and syngeneic tumour cells. Again the H–2 region seems to have a major role in an immunosurveillance phenomenon as reported previously for non-oncogenic virus infections, including lymphocytic chriomeningitis[4], vaccinia[11] and ectromelia[12], after immunisation by hapten-modified cells[5,6]; and in the immune response against non-H–2 antigens of normal lymphoid cells[10]. Similar results have also been found in tumours induced by Friend leukaemia virus[13] and during *in vitro* stimulation of anti-MSV CTL by tumour cells (F. Plata, personal communication). It is generally assumed that the antigen reacting with CTL is an H–2 modified specificity[4,6,11,12]. MSV and Friend systems are especially interesting in this case, since the viral polypeptides reacting with H–2 molecules can probably be determined. Further studies are in progress to try to clarify this point and to define the H–2 products involved· H–2D, H–2K or Ia determinants. Preliminary results show that H–2D antigens are especially important.

Another hypothesis must be considered. It has been shown that an H–2 compatibility betwen CTL and targets is necessary in the CTL reaction directed against non-H–2 antigens of normal lymphoid cells[10]. In this situation H–2 and non-H–2 determinants are presumably not on the same structure, and the hypothesis of an *H–2* region product specifically modifying non-*H–2* molecules must therefore be considered[10]. The same could be true in the MSV system: it cannot be excluded, for example, that the antigenic determinants of the major glycoprotein 69/71 of the virus could be modified by an *H–2* region-directed molecule. Therefore the nature of the relationship between H–2 and virus antigens is not clearly defined, at least in the MSV system.

Whatever the nature of the H–2/MSV interactions, the existence of an H–2 barrier to the action of anti-virus producer cell CTL merits two comments of practical value. (1) The antigens reacting with CTL in MSV tumour-bearing mice are not completely understood since FMRGi, due to the Moloney virus[3,8], and MEV.SA1 antigen, due to endogenous viruses[14], are involved. From the experiments with H–2 congenic lines we can assume that, if an endogenous virus antigen is the target of the anti-MSV CTL it must be integrated in the *H–2* region and it has followed this region during the selection of BALB.B and B10.D2 congenic lines. Another, less probable, hypothesis would be that two endogenous viruses of different antigenicity are present both in BALB/c and in B6, their expression being controlled separately by different locus of the *H–2* region. It is more likely that FMRGi or other antigens, due to the MSV or to its helper virus, are the main targets of CTL, their specificities being modified according to the H–2 of the host. Note, however, that an H–2 incompatibility strongly decreases but does not completely suppress tumour

Table 3 Blocking of anti-MSV CTL induced cytolysis by preincubation of anti-H–2 antibodies with the target cells

Antisera	Specific chromium release by MBL2 targets (%)
C normal serum	18
C anti-B6	0
C anti-B6 absorbed in BALB.B	17
C anti-B6 absorbed in B10.D2	4
C anti-BALB B	0
B6 anti-C	19
AKR anti-Thy 1–2	19

cells lysis by CTL, since highly potent CTL can be weakly efficient against allogeneic cells of different H-2 (refs 8 and 14). This could be due to the existence of different subpopulations of immune CTL, some of them reacting, for example, with antigens unrelated to H-2. (2) If HLA has the same role in humans as H-2 in mice, study of antitumour cell reaction due to CTL in cancer patients must be carried out in autologous conditions or, at least, between CTL and target cells sharing HLA determinants. Negative results would otherwise be of little significance.

Plasmin-mediated agglutination by concanavalin A of 3T3 cells cocultured with SV40–3T3 transformants

REICH and colleagues have reported that a variety of embryo fibroblasts in tissue culture show fibrinolytic activity after viral transformation[1,2]. This effect is attributable to the action of a plasminogen activator, which is a serine protease[3] and is present at higher concentrations in transformed than untransformed fibroblasts[4]; this activator converts plasminogen, present in the serum, to the fibrinolytic enzyme plasmin[5,6]. Certain characteristics of transformed cells, such as altered morphology and multilayering, may be plasmin dependent[7,8]. Plasmin may also induce changes in untransformed cells; this is supported by the observation that normal fibroblasts cocultured with viral transformants developed similar morphology to that of the transformed cells[8]. Furthermore, proteolytic activity released from transformed cells induced lectin-mediated agglutination, and stimulated thymidine incorporation in non-dividing cultures of untransformed fibroblasts and epithelial cells[9]. The possibility therefore exists that untransformed cells may express in coculture certain features of transformed cells as a result of environmental plasminogen activation. In support of this we report here the plasminogen-dependent enhancement of agglutination by concanavalin A (con A) of untransformed cells in coculture with transformed cells.

Table 1 Agglutination by con A of 3T3 cells in monoculture and in coculture with SV40–3T3 cells

Serum supplement (10%)	Agglutination (monoculture)	Agglutination (coculture)	Net increase
Calf	1	8	7
Foetal calf	1	8	7
Horse	2	8	6
Pig	5	8	3
Chicken	1	6	5
Human	3	7	4
Guinea pig	3	7	4
Rabbit	1	7	6

To prevent mixing, the two cell types were initially seeded separately on microscope slides anchored down with silicone grease in square Petri dishes untreated for tissue culture. They were then incubated for 24 h in Dulbecco's modified Eagle's medium+10% foetal calf serum. The slides of subconfluent cells were then thoroughly washed in serum-free medium, and transferred to new dishes for mono- or coculture in media supplemented with the sera listed. After 24 h they were washed twice and the cells were resuspended by incubating for 1 h in Ca^{2+}- and Mg^{2+}-free phosphate-buffered saline (PBS) Agglutination was then carried out in complete PBS+100 μg ml^{-1} con A in conical plastic tubes which were shaken at 100 r.p.m. for 30 min at 37 °C. Agglutination was then assessed on a 0–10 scale by 10 independent observers and an average unit value obtained.

Swiss mouse 3T3 cells and SV40–3T3 transformants were used. We found that when 3T3 cells were grown in various sera they were generally only slightly agglutinable; however, when cocultured with SV40–3T3 cells they became highly agglutinable irrespective of the type of serum used (Table 1) Since contact between the two types of cell in coculture was only through the medium, this enhancement is attributable either to the release of an SV40–3T3 cell effector substance or to the activation of a medium factor by an SV40–3T3 cell activator substance. The release of one or other of these agents into the medium was demonstrated when 3T3 cells incubated in serum-free medium conditioned by four 24-h exposures to SV40–3T3 cells showed enhanced agglutination in con A compared with those incubated in unconditioned medium (Table 2). The lower level of agglutination enhancement achieved in this case when compared with 3T3 cells cocultured for a single day in unconditioned medium (Table 1) suggests that the major part of the SV40–3T3 cell agent was cell associated. This tends to support the view that enhanced 3T3 cell agglutinability required the interaction of a cell activator substance with a component of the medium. We confirmed this by failing to enhance the agglutination of 3T3 cells in the absence of serum (Table 2). Consequently, the enhancement of 3T3 cell agglutination is attributable to the interaction of an activator of SV40–3T3 cell origin with a serum component. Plasminogen is a serum component and its activated form, plasmin, is a protease with trypsin-like specificity[10] Since trypsin is known to induce con A agglutination of 3T3 cells[11] the enhanced agglutinability of 3T3 cells exposed to SV40–3T3 cell activator may be due to the conversion of serum plasminogen to plasmin. To test this we attempted to induce con A agglutination enhancement in cocultured 3T3 cells in serum-free medium to which plasminogen was added. After 24 h of coculture 3T3 cells became agglutinable, but cells incubated without plasminogen, SV40–3T3 cells, or both, failed to

Table 2 Agglutination by con A of 3T3 cells incubated in SV40–3T3 cell-conditioned medium

Serum supplement	Agglutination in unconditioned medium	Agglutination in conditioned medium	Net increase
10% calf	1	5	4
None	1	1	0

Serum-free Dulbecco's modified Eagle's medium was conditioned by exposure to SV40–3T3 cells for four separate 24-h periods, between each of which it was stored at −20 °C while the cells were allowed to recover for 24 h in foetal calf serum-supplemented medium. Before incubating with the 3T3 cells for 24 h the conditioned medium was filtered through 0 22 μm pores to remove any cells. 10% calf serum, selected for high agglutinating activity (Table 1), was added to the conditioned and unconditioned media The subsequent incubation and agglutination procedures were as described in Table 1.

Table 3 Agglutination by con A of 3T3 cells in coculture with SV40–3T3 cells in serum-free medium containing plasminogen

Cocultured with SV40–3T3 cells	Medium supplement	Agglutination
+	Plasminogen	4
–	Plasminogen	1
+	None	1
–	None	1
+	Plasminogen	1 (no con A added)
–	10% foetal calf serum	1

Cells were grown on microscope slides as described in Table 1 After washing they were incubated for 24 h in the conditions shown; lyophilised pig blood plasminogen was added at 20 μg ml^{-1}. Since cells incubated without serum were more readily detached from the substrate than those incubated with serum, the incubation in Ca^{2+}- and Mg^{2+}-free PBS was reduced to 10 min in these groups. Agglutination was carried out as described in Table 1.

agglutinate (Table 3). Consequently, enhanced agglutination is attributable to the interaction of SV40–3T3 cell activator and plasminogen. Using the casein–Agarose overlay assay[4], we found that detectable digestion of casein was produced by SV40–3T3 cells, but not by 3T3 cells, in media supplemented with any of the sera listed in Table 1. This supports the view that the SV40–3T3 cell factor is a plasminogen activator which converts added or serum plasminogen to plasmin, and that it is present at lower activity in, or absent from, 3T3 cells.

It has been reported[12] that human uterine cervix fibroblasts, normally not agglutinable with con A, show increasing agglutination as adjacent lesions of the overlying epithelium progress from dysplasia through *in situ* carcinoma to invasive carcinoma. There may be a close parallel between these changes and the plasmin-mediated enhancement of agglutination in con A of cocultured 3T3 cells reported here Since primary cultures of malignant tissues may often have high concentrations of plasminogen activator compared with normal tissues[13], the increasing agglutination of normal fibroblasts adjacent to these neoplastic lesions may be attributable to a local conversion of serum plasminogen into plasmin by increasing concentrations of tumour cell plasminogen activator. This suggests the interesting possibility that tumours may be associated with normal cells in a "quasi-malignant" state, expressing one or more features usually considered to be characteristic of malignant transformation.

Transformation of C3H/10T1/2 CL8 mouse embryo fibroblasts by ultraviolet irradiation and a phorbol ester

Ultraviolet light is the major cause of human skin cancer, and papillomas and malignant carcinomas have been induced in the skins of rats and mice by repeated exposure to it[1–5]. Pound[6] reported that although a single short exposure of mouse skin to ultraviolet light did not induce any tumours, when the single exposure was followed by repeated applications of croton oil, many tumours were induced Thus ultraviolet light acted as an initiator in the two-stage process of skin tumour development[7,8]. X rays can induce oncogenic transformation of cells in culture[9,10], and a preliminary report has appeared on the transformation of hamster embryo cells by ultraviolet light[11].

We have developed a cloned line of C3H mouse fibroblasts, C3H/10T1/2 CL8, which is non-malignant and highly susceptible to postconfluence inhibition of cell division[12]. These cells are transformed to malignancy with polycyclic hydrocarbon carcinogens and by certain alkylating agents[13], and the response can be quantified. We have also reported[14] that when these cells were treated with a subeffective concentration of polycyclic hydrocarbons followed 5 d later by a non-transforming and non-cytotoxic concentration of tetradecanoyl phorbol acetate (TPA, 0.1 μg ml^{-1})[15], transformation occurred. Thus, initiation and promotion have been achieved with our system of cultured cells. The transformed foci so obtained are of type. III, (ref. 13) which give rise to fibrosarcomas in syngeneic mice[13].

In our experiments, 2,000 C3H/10T1/2 cells were plated in 60-mm Falcon dishes in Eagle's BME medium + 10% heat-inactivated foetal calf serum (Gibco). Twenty-four hours later the cells were irradiated once in fresh medium with an ultraviolet lamp (Dazor) with doses from 10 to 100 ergs mm^{-2}. The dose of ultraviolet irradiation was measured by an ergometer (Ultra-Violet Products) in ergs mm^{-2} s^{-1}. After irradiation the cells were given fresh medium and incubated in a humidified incubator (Forma) at 37 °C in an atmosphere of 5% carbon dioxide in air. After various times some of the cultures were given TPA (0.1 μg ml^{-1}) in the medium for the remainder of the experiment. TPA (Consolidated Midland) was dissolved in spectrograde acetone and stored in amber bottles at −20 °C. It was added to the medium so that the final concentration of acetone was 0.5%. The cytotoxicity of the ultraviolet irradiation was determined by its effect on the plating efficiency of 200 cells, and the colonies were

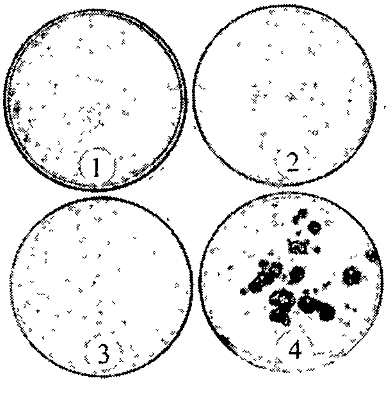

Fig. 1 Fixed and stained dishes of C3H/10T1/2 CL8 cells 6 weeks after initial treatment: 1, 0.5% acetone; 2, TPA 0.1 μg ml^{-1}; 3, ultraviolet light, 25 erg mm^{-2}; 4, ultraviolet light, 25 erg mm^{-2}, followed 48 h later by TPA 0.1 μg ml^{-1}.

Table 1 Transformation of C3H/10T1/2 CL8 cells by ultraviolet light and TPA

Treatment schedule	Plating efficiency %	No. of dishes with foci/total no. of dishes	% Dishes with foci	Transformation frequency*
0.5% Acetone	19	0/23	0	0

48 h	1	6/15	40	3.7
72 h	1	8/17	47	2.6
96 h	1	3/12	25	1.7
120 h	1	3/11	27	1.4

The concentration of TPA used was 0.1 µg ml^{-1}.
* Percentage transformed foci per surviving cell plated
† Time after irradiation when TPA was added.

counted after 8–10 d (ref. 13). Type III transformed foci were scored 6 d after fixation with methanol and staining with Giemsa, which was 6 weeks after 2,000 cells had been plated in 60-mm dishes, as described previously[10,13].

The results are shown in Table 1. Ultraviolet irradiation at 10 and 25 erg mm^{-2} was not cytotoxic, but larger doses were No type III transformed foci were obtained in the acetone control dishes, in the dishes treated with TPA (1 µg ml^{-1}) or in the dishes treated with ultraviolet irradiation. When TPA was added to the medium 48 h or more after irradiation, however, significant numbers of transformed foci were observed (Table 1 and Fig. 1). This transformation was dose dependent for ultraviolet irradiation, with high transformation frequencies, corrected for cytotoxicity, for 100 erg mm^{-2} followed by TPA. In general, the transformation frequency decreased if TPA treatment started 96 h or more after irradiation.

These experiments show that ultraviolet light acts as an initiator of transformation in our cells, just as it did in the experiments on mouse skin[6]. This first success in achieving transformation in cell cultures with ultraviolet light will lead to important information on the mechanism of ultraviolet carcinogenesis Relevant studies, with particular emphasis on DNA repair, are in progress.

Increased procoagulant activity in cultured fibroblasts from progeria and Werner's syndromes of premature ageing

BIOLOGICAL ageing undoubtedly involves a number of complex physiological and biochemical factors but it is increasingly evident that the cultured human fibroblast will help to elucidate the fundamental nature of this process. These cells have a finite replicative lifespan that is inversely related to the age of the donor[1–3]. Moreover, physiological rather than chronological age is a critical determinant, since cultured fibroblasts from the progeria and Werner's syndromes of premature ageing have significantly reduced growth potential compared with normal, age-matched controls[3–5] Although the decreased replicative ability of cells may help to explain some of the features of progeria and Werner's syndrome, such as stunting of growth and impaired wound healing ability, it does not explain other pathological concomitants of these disorders. In particular, an explanation is needed for the premature appearance of severe atherothrombotic disease[6,7]. It has been shown that human fibroblasts contain a potent procoagulant activity called 'tissue factor' (TF)[8]. TF has the capacity to activate the extrinsic clotting mechanism through factor VII, eventually leading to thrombin generation which then promotes clot formation through fibrinogen[8,9] We report here that skin fibroblasts derived from subjects with progeria and

Werner's syndrome have markedly elevated levels of TF compared with controls.

Fibroblast strains were initiated from skin biopsies of three male subjects with classical progeria, one aged 2.5 yr and two aged 9 yr, and a 56-yr-old woman with Werner's syndrome, following informed consent of the subjects or their parents. Clinical details on two of the progeria subjects[10] and the subject with Werner's syndrome[3,6] have been published. Normal control cultures were derived from donors aged 22–76 yr, whereas abnormal controls were two subjects aged 5 yr with Lesch–Nyhan syndrome and homocystinuria. The latter two were better matched to the progeria subjects in terms of age, stunting of growth and chronic illness, all of which could possibly affect the growth of cultured cells and the amount of TF activity All cultures were initiated and propagated in our laboratory using Eagle's medium supplemented with non-essential amino acids and 15% foetal calf serum as described previously[2,10]. Subcultivation was carried out at a 1·8 split ratio counting three mean population doublings each time, until exhaustion of the replicative potential[1–3]. By this criterion, control cells had replicative lifespans ranging from 48–75 doublings, progeria cells 21–40 doublings, and Werner's strain only 15 doublings. Control cells were assayed for TF both at early and late passage, the latter 3–9 doublings before termination. Progeria cells were assayed with 9–30 doublings remaining and Werner's cells within 3–6 doublings of termination. In preparation for assay of TF activity, post-confluent sheets of cells were collected by a routine trypsinisation method[1–3] that was strictly standardised. Cells were incubated with a 0.125 trypsin solution (Difco 1:250) at 37 °C for exactly 10 min, after which the trypsin was neutralised with a 20-volume excess of growth medium containing 15% foetal calf serum. When soybean trypsin inhibitor was used to neutralise trypsin, essentially identical results were obtained in the TF assay.

Figure 1 is a combined plot of TF activities in the various fibroblast strains. TF in control cells ranged from 2 to 12 U per 10^6 cells with a mean of 5.06 U ± 3.84 (s.d.). No effect of donor age was evident. In striking contrast, progeria and Werner's cells showed significantly elevated TF activities, ranging from 23 U to a maximum of 137 U Since the anatomic site of biopsy can influence various parameters in cultured fibroblasts[3], assays on cell strains derived from skin of the anterior forearm of the 2.5- and 9-yr-old progeria subjects ($n = 16$) were compared with controls, all derived from the same anatomic site ($n = 41$). The differences remained highly significant ($P < 0.01$). Slow growth *per se* of the prematurely ageing cells could not account for these findings; when control cells were assayed during their senescent phase, with 3–9 mean population doublings remaining until termination of growth, the mean TF activity was 7.96 ± 6.82 U, still significantly different from progeria strains ($P < 0.01$). Additionally, control strains from aged adults, with growth properties similar to progeria cells[10] had substantially lower TF activities (Fig. 1). The apparent increment in TF activity during the lifespan of control cells was not statistically significant.

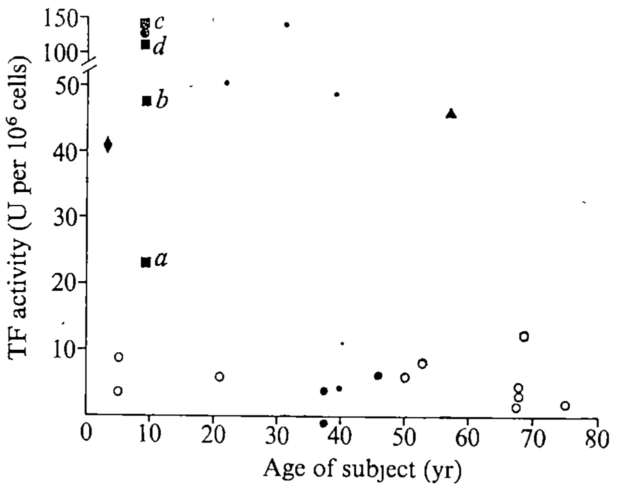

Fig. 1 TF activity of early passage fibroblasts as a function of the age of donor. The assay was slightly modified from the one-stage thromboplastin method of Zacharski and McIntyre[8]. Collected cells were suspended and rinsed twice in PBS and then in Tyrode's albumin buffer[11]. The final suspension of washed fibroblasts was adjusted to 2×10^6 cells ml^{-1}. Platelet-poor citrated human plasma obtained from healthy donors and the plasmas of patients with hereditary factor VII and factor VIII deficiency (Dade Division, American Hospital Supply Corporation, Miami, Florida 33152) were used as substrates. To carry out the clotting assay, 0.1-ml aliquots of plasma were incubated in a water bath at 37 °C, followed by addition of 0.1 ml fibroblast suspension and 0.1 ml 0.025 M $CaCl_2$. The clotting times were recorded and the procoagulant activity of fibroblasts was compared with that of rabbit brain thromboplastin (Thromboplastin reagent, Dade). We accepted arbitrarily that 1 ml of this reagent contained 1,000 U TF. Thromboplastin was serially diluted up to 1:5,120 in Tyrode's albumin buffer and the effect of each dilution was tested on the clotting time. The clotting time of normal human plasma without rabbit brain thromboplastin was approximately 210 s, whereas the sample with concentrated thromboplastin clotted in 14–15 s. Since dilution curves obtained using rabbit brain thromboplastin and fibroblasts were of a similar character, TF activity of fibroblasts was expressed in arbitrary units calculated by intrapolation. Each fibroblast suspension was assayed at a minimum of four cell concentrations. Progeria (solid symbols), Werner's syndrome ▲, and normal controls (open symbols). *a*–*d*, Single subject with progeria using individual cultures initiated from skin of various anatomic sites: *a*, anterior forearm; *b*, anterior thigh; *c* and *d*, bilateral calves. Strain ● originated from skin over the lumbar area, whereas all other cultures originated from skin of the anterior forearm. Values are means of 3–14 experiments except for *b*, *c* and *d*, which represent single observations.

Disruption of cells by sonication produced about a fivefold increase in TF activity in all strains but the differences between controls and prematurely ageing cells were maintained. This suggests that the higher levels of TF in progeria and Werner's cells relate primarily to increased content rather than increased availability. The supernatant obtained following 300*g* centrifugation of cells collected by trypsinisation and neutralised with soybean trypsin inhibitor was also assayed, but no TF activity could be detected. In contrast, control supernatants, obtained after incubating monolayers with enzyme-free buffer, contained about 10% of the total TF in the system (cells plus supernatant). These results

Table 1 Effect of cultured skin fibroblasts on clotting time of recalcified plasma in presence of normal and factor-deficient plasma

Additive	Clotting time (s) Type of plasma Normal		Factor VII-deficient		Factor VIII-deficient	
	Expt 1	Expt 2	Expt 1	Expt 2	Expt 1	Expt 2
Control (Tyrode's fluid alone)	186	166	227	154	527	510
Normal cells	49	80	176	145	58	61
Progeria cells	31	53	120	123	36	31

Early passage cells from 22-yr-old normal male and 9-yr-old boy with progeria were used.

are in conflict with a report using more purified trypsin[12] and suggest that different experimental techniques may be responsible. For example, the relatively crude pancreatic trypsin used in our studies may contain other enzymes such as lipases capable of digesting an essential lipid component of TF[12,13].

To determine whether fibroblast TF was specific for the extrinsic clotting mechanism (that is, activation via factor VII), experiments were carried out with intact cells using plasma from patients with hereditary deficiencies of clotting factors (Table 1). With factor VII-deficient plasma, both normal and progeric cells showed a markedly prolonged clotting time, much like the control fluid without cells. When factor VIII-deficient plasma was used, however, the clotting time was again shortened to resemble values observed with normal plasma. In total, these data strongly suggest that the extrinsic rather than the intrinsic clotting mechanism plays an important role in the TF-mediated clotting.

To determine whether TF itself was responsible for the increased procoagulant activity, cells were preincubated with specific immune globulins directed against purified TF followed by assay (Fig. 2). Both normal and progeria cells showed a progressive prolongation of the clotting time after treatment with the specific immune globulins, but not with preimmune globulins or normal saline. This indicates that fibroblast TF is similar or identical to the placental TF used as antigen, and further, that both can stimulate clotting through the extrinsic mechanism.

It is not clear why cells from two genetically distinct disorders[6,7] show similar elevations in TF activity. Reports indicate that progeria and Werner's cells contain a diversity of altered proteins affecting HLA antigens, cytoplasmic enzymes[10,14–16] and insulin receptors[23]. Thus, although the TF of prematurely ageing cells seems to be recognised normally by specific antiserum, it may have a structural alteration such that a given amount possesses increased procoagulant activity.

An explanation is also needed for how an increased amount of procoagulant in prematurely ageing skin fibroblasts could relate to the severe vascular disease of progeria and Werner's syndrome[6,7]. Indeed, it would be extremely useful to know the TF activity and growth potential of fibroblasts from a second set of controls, subjects with severe atherothrombotic disease apart from progeria and Werner's syndromes. Such studies, now in progress, may confirm that increased procoagulant activity and impaired growth potential are important factors in atherothrombosis when they involve certain cells within the vascular tree[14]. In fact, there is evidence that the cultured 'fibroblast' may originate from vascular cells such as endothelium or pericytes[17,18]. The early concept of Rokitansky[19], still extant today[20,21], proposes that coagulation mechanisms acting in or on arterial walls contribute to atherosclerosis. Zeldis *et al.*[22] have found that plasma membranes of intimal and medial cells are rich in TF antigen, in large blood vessels and their vasa vasorum. Moreover, TF is particularly abundant in the vicinity of atherosclerotic plaques where it virtually encompasses cholesterol crystals. Thus, TF could initiate coagulation not only as a consequence of plaque disruption but also after minimal cellular damage[12,22]. In any case, it is possible that elevated TF in arterial cells is an important factor that predisposes individuals with progeria and Werner's syndromes to an increased risk of thrombosis, atherogenesis and premature death.

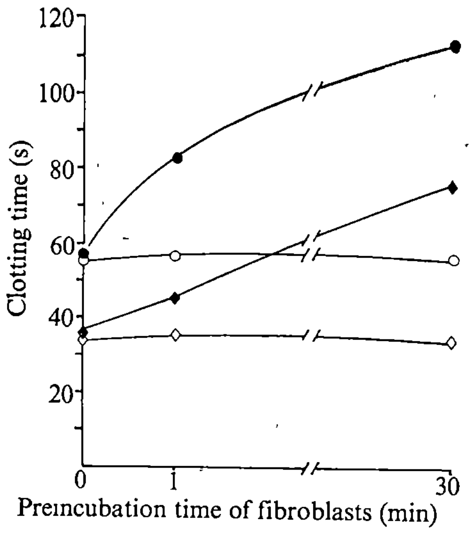

Fig. 2 TF activity of cultured fibroblasts incubated with and without specific immune globulins against purified TF. Fibroblasts were preincubated with immune globulins, preimmune globulins, or 0.9 NaCl and then assayed for TF. Early passage cells from a 22-yr-old normal male and from the 2.5-yr-old boy with progeria were used. ●, Normal cells+immune globulins; ◆, progeria cells+immune globulins; ○, normal cells+0.9% NaCl or preimmune globulins; ◇, progeria cells+0.9% NaCl or preimmune globulins.

We thank C. Lowery and E. Moerman for assistance and Dr Y. Nemerson for antiserum to TF. Supported by the NIH the MRC of Canada, the Canadian Diabetic Association Foundation Fund and the Ontario Heart Fund during the tenure of a MRC Scholarship to S.G.

Thymic factor in human sera demonstrable by a cyclic AMP assay

NORMAL human serum has been reported to contain thymus hormone activity as detectable by a rosette inhibition assay[1]. It has been suggested that this circulating hormone may act through stimulation of cyclic AMP synthesis[2]. In addition, other thymic hormones isolated from the thymus, such as thymosin[3] and THF[4], have been found to activate membrane adenylate cyclase and to increase cellular levels of cyclic AMP in thymocytes[5,6]. Thymopoietin, a thymic hormone

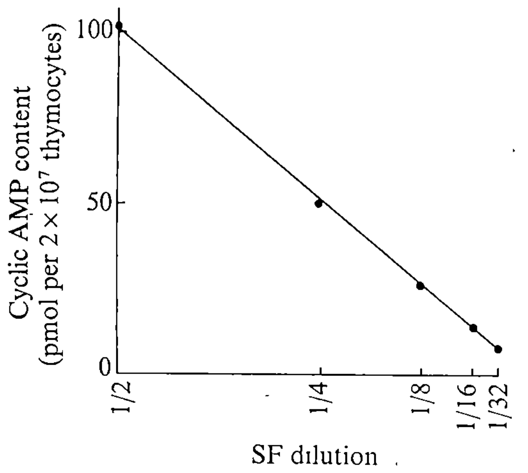

Fig. 1 Effect of different dilutions of SF on cellular cyclic AMP level. Human serum was collected by centrifugation at 4 °C after defibrination of the blood Serum was filtered on Amicon membrane CF50 (nominal cut-off molecular weight 50,000) by which high molecular weight thymic hormone inhibitors were removed[9]. Ultrafiltrate was added at different dilutions to Earle's solution containing thymocytes obtained from C57BL/6 mice aged 4–8 weeks. Cell concentration was adjusted to 2×10^6 cells ml^{-1}. After 5 min of incubation at 37 °C cellular cyclic AMP was extracted, placing tubes in liquid nitrogen for 1 min and subsequently in a boiling water bath for 5 min. Coagulated proteins were spun down in the cold and the supernatant directly assayed in duplicate, by Gilman's competition-binding procedure[10] with a cyclic AMP assay kit (TRK432, The Radiochemical Centre).

the amino acid sequence of which has been established[7], has also been claimed to induce T-cell differentiation by way of cyclic AMP[8] Here we report on a human serum factor (SF) capable of increasing the level of cellular cyclic AMP in thymocytes; we also present evidence for the possible thymic nature of this factor.

Figure 1 shows the effect of SF from a normal 18-yr-old donor on cyclic AMP levels in mouse thymocytes. Similar results were obtained with human thymocytes Among sera from different donors a marked variability in SF activity was observed. The differences in the increase of cyclic AMP levels were, however, in no way correlated with the cyclic AMP content of the sera (correlation coefficient=0.0304, $n=19$). In an attempt to establish the thymic origin of the SF we investigated sera from a total of 18 thymectomised myastenic patients (mean age 35.6 yr, s.d. 13.8). The SF activity was virtually absent in the thymectomised donors (mean 12.64 pmol cyclic AMP/2×10^7 cells, s.e. 1.96), whereas in normal healthy individuals ($n=399$; mean age 26.7 yr, s.d. 7.8) and in non-thymectomised myastenic patients ($n=5$; mean age 47 yr, s.d. 13.3) was consistently demonstrable (mean 76.69 pmol cyclic AMP/2×10^7 cells, s.e. 6.2; and mean 92.80 pmol cyclic AMP/2×10^7 cells, s.e. 21.81, respectively) When SF from normal donors was mixed with a similarly prepared material from thymectomised, no decrease in the activity was observed. The presence of SF inhibitors in the SF from thymectomised was therefore ruled out.

Table 1 Effect of adsorptions on SF activity

	pmol per 2×10^7 thymocytes
No SF added	12.8±0.8
SF (dilution 1:4)	61.8±2.5
SF (1:4) adsorbed on human thymocytes	11.0±1.4
SF (1:4) adsorbed on mice thymocytes	18.2±0.5
SF (1:4) adsorbed on human granulocytes	61.8±7.6
SF (1:4) adsorbed on mouse liver cells	88.4±0.6

Results are expressed as mean ± s.e of four experiments. SF was incubated for 1 h at 37 °C either alone or in the presence of 1×10^9 lyophilised human thymocytes or granulocytes per ml SF. When viable mouse thymocytes and liver cells were used for adsorption, the ratio of 4×10^8 cells per ml SF was used

We also investigated the binding capacity of SF to different cell types. To this end, adsorption experiments were carried out. It was found that SF activity could be completely adsorbed by lyophilised human thymocytes as well as by viable mouse thymocytes. On the other hand, adsorption with either lyophilised human granulocytes or viable mouse liver cells did not lead to a diminution of SF activity (Table 1).

Finally, the target specificity of SF and a number of agents known to elevate cellular cyclic AMP were tested on a panel of different mouse cells (Table 2). It seems therefore that SF is increasing cyclic AMP levels mainly in thymocytes with little or no effect on other lymphoid cells. In contrast, nonspecific stimulators of cyclic AMP, such as isoproterenol and prostaglandin E_1 (PGE_1), showed a marked stimulation in all target cells tested. Note that the increase in cyclic AMP in thymocytes given by the β-adrenergic activator isoproterenol could be selectively inhibited by the antagonist propranolol. Since the effect of SF is not inhibited to any extent by propranolol (Table 3), it seems that SF is acting through a membrane site, probably a receptor distinct from that for β-adrenergic activators. When isoproterenol and SF were added together, only a partial additive stimulation occurred. This indicates that, although they act on distinct membrane sites, isoproterenol and SF may stimulate the same adenylate cyclase regulatory subunit, as proposed for thymic hormones[8] The combination isoproterenol, propranolol and SF produced a similar increase in cyclic AMP as did SF alone, again indicating that the antagonism isoproterenol–propranolol did not interfere with

Table 3 Effects of SF, isoproterenol and propranolol on cyclic AMP level in thymocytes

	pmol per 2×10^7 thymocytes
No SF added	12.4±0.6
SF (dilution 1:4)	72.3±3.5
Isoproterenol (10^{-5}M)	220.9±1.0
Propranolol (10^{-5}M)	11.7±0.8
SF (1:4) + isoproterenol (10^{-5}M)	236.7±16.2
SF (1:4) + propranolol (10^{-5}M)	76.1±8.1
Isoproterenol (10^{-5}M) + propranolol (10^{-5}M)	10.5±0.1
SF (1:4) + isoproterenol (10^{-5}M) + propranolol (10^{-5}M)	77.5±2.3

Results expressed as mean ± s.e. of four experiments.

Table 2 Effects of SF and drugs on cyclic AMP levels in different target cells

	Thymocytes	Spleen cells	Lymph node cells	PBL*	Liver cells
No SF added	10.3±0.3	11.7±1.4	23.0±0.2	37.2±1.3	15.3±0.9
SF (dilution 1:2)	139.1±1.3	17.2±1.0	56.7±4.0	28.8±1.7	13.7±0.8
PGE_1 (10^{-6}M)	151.8±9.9	42.7±6.8	107.0±3.7	113.1±1.6	47.0±0.8
Isoproterenol (10^{-5}M)	218.8±1.1	46.5±9.3	83.1±2.0	81.4±1.7	37.4±1.3

*Human peripheral blood lymphocytes

the capacity of the cells to respond to SF by an increased cyclic AMP level.

In conclusion, SF seems to be thymus derived, since the activity in thymectomised patients is absent. Furthermore, among the different target cells investigated, only thymocytes were found to possess a membrane site for SF in addition to the β-adrenergic receptor. Experiments are now being carried out to establish whether SF has the biological activity of the thymic hormone described by Bach *et al*[1]. The stimulation of cyclic AMP synthesis on thymocytes will eventually provide a quantitative and reproducible assay for the detection of human circulating thymic hormone.

Lack of an autosomal recessive genetic influence in vertical transmission of hepatitis B antigen

BLUMBERG *et al* have postulated that predisposition to the hepatitis B antigen (HBsAg) carrier state is inherited as an autosomal recessive gene[1]. Crucial to this concept, but lacking in Blumberg's populations, are families in which both parents are carriers. All offspring of such families should be homozygous for carrier predisposition and once infected all should become carriers. To test Blumberg's hypothesis, we compared rates of hepatitis B antigenaemia among children in two groups of families: those in which both parents were HBsAg carriers and those in which the mother was a carrier, but the father's serum was antibody (anti-HBs) positive. We did not include families when the father's serum was both HBsAg and anti-HBs negative, since carrier state predisposition remained unknown without evidence of previous hepatitis B virus (HBV) infection. If the autosomal recessive genetic hypothesis is correct, we would expect, in families with two HBsAg carrier parents, that all HBV-infected offspring would become carriers. In contrast, only a small proportion of children would become carriers in families with a carrier mother and an antibody-positive father, since most children would have only a single gene for carrier predisposition (inherited from their mothers) and would, like their fathers, form antibody after exposure rather than becoming carriers.

The families in this study were derived from a study of vertical transmission of the hepatitis B virus from carrier mothers in Taiwan to their newborn offspring. The details of the population studied and methods used have been published before[2,3]. Sera of newborns were tested periodically for HBsAg and anti-HBs, and other family members' sera were tested at least once. We have included here all families in which the mothers' sera contained HBsAg and the fathers' sera contained either HBsAg or anti-HBs. Data are included only on children who were at least 3 months old (when most babies who became carriers were first known to be HBsAg positive)[2].

Hepatitis B surface antigen was detected in all specimens by radioimmunoassay (RIA, AUSRIA-I™, Abbott Diagnostics)[4] and complement fixation (CF)[5,6]. Babies' sera were retested by the more sensitive AUSRIA-II™, so rates of antigenaemia among the babies are higher than described previously[2]. Antibody (anti-HBs) was detected by passive haemagglutination (PHA-Electronucleonics) with titres of 1 : 8 or greater considered positive[7].

The frequency of antigenaemia among the offspring (both the babies and their siblings) was unrelated to whether their father's serum was antigen or antibody positive (Table 1). Babies in both groups were followed from birth for the same time (mean, 12 months) and none of the babies or their siblings had clinical hepatitis. All but five of 27 babies retested after their first positive specimens (eight of nine with an antigen-carrier father and 14 of 18 with an antibody-positive father) remained HBsAg carriers (average of 11 months follow-up). One further baby in each group developed anti-HBs (neither had had previously detected antigenaemia). The geometric mean CF titre (GMT) for the mothers of the seven babies with either transient antigenaemia or antibody was 1 : 5.9±3.1 (± 1 s.d.), whereas the GMT for those who became carriers was 1 : 46.1±2.8 (± 1 s.d.). Only seven siblings (9.5%) had anti-HBs-positive sera (one of 27 with a carrier father and six of 47 with an antibody-positive father).

Blumberg's autosomal recessive genetic hypothesis for predisposition to the HBsAg carrier state has evoked considerable controversy[8]. The data from several large population studies are compatible with such an explanation for the observed carrier segregation[1,9–11]. Mazzur has reported retrospective evidence of vertical transmission among Blumberg's original populations[12]. These data, in spite of the evidence of vertical transmission, remain compatible with an autosomal recessive mode of inheritance for carrier predisposition, although again lacking two carrier parent families.

Such family clustering of HBsAg carriers could also be explained, as Lederberg and Petrakis pointed out, by the spread of an infectious agent through close personal contact, without any genetic influence[13,14]. Information from families with the critical matings of two HBsAg-carrier parents has been difficult to obtain, especially in countries with a low carrier prevalence. During a study of vertical transmission of HBV from antigen-carrier mothers to their newborn offspring in Taiwan (a high prevalence area), we found a large number of families with two antigen carrier parents. Data from these families, compared with those with a carrier mother and an antigen-negative, antibody-positive father, were incompatible with an autosomal recessive mode of inheritance. Whether the father was an HBsAg carrier or was antibody positive had no influence on the development of chronic antigenaemia in the newborn children or its existence in their siblings. The maternal CF titre, on the other hand, did influence the baby's response to HBV infection (transient antigenaemia, the development of anti-HBs, or a chronic HBsAg carrier state). In addition, we have reported previously that virtually 100% of babies and their siblings were chronic HBsAg carriers when the mother's serum had a very high CF titre (⩾1 : 64) (ref. 2).

Our findings suggest that all these children could become

Table 1 Hepatitis B antigenaemia among offspring of HBsAg carrier mothers: influence of HBsAg or anti-HBs status of fathers

Father	Babies No. of HBsAg positive/total*	Babies % Positive	Siblings No. of HBsAg positive/total*	Siblings % Positive
HBsAg positive	13/22	59.1	17/27	63.0
Anti-HBs positive	30/53	56.6	27/47	57.4

*$P > 0.5$ by χ^2.

HBsAg carriers, regardless of their genetic background. Development of the carrier state was probably influenced more by the dose of infectious virus they received (as suggested by the relationship between antigenaemia among the children and their mothers' CF titres). Schweitzer made a similar observation in his finding that vertical transmission from HBsAg carrier mothers in the USA only occurred when the mother's serum contained the e antigen (thought to be related to HBV infectivity)[15,16]. The early age of exposure in these children may also be important, since the age when infection occurs has been shown to influence the development of the carrier state in other settings[17]. Our data support this concept, since very few children had anti-HBs, indicating that when HBV infection occurred early in life, nearly all who were infected became carriers.

In summary, the data presented here seem to be incompatible with an autosomal recessive mode of inheritance for HBsAg carrier predisposition. It seems instead that the infectious dose and the age when infection occurs are more important determinants of the carrier state. The discrepancy between our findings and those of population studies may also indicate that family segregation analyses, especially of a contagious disease, cannot readily discriminate between the roles of environmental and genetic factors[18].

This study was supported through funds provided in part by the Naval Medical Research and Development Command, US Navy Department, and the Office of Naval Research.

Human foetal pituitary peptides and parturition

THE pituitary gland produces a family of related peptide hormones (Fig. 1). Adrenocorticotrophic hormone (ACTH), β-lipotropic hormone (β-LPH) and possibly γ-lipotropic hormone (γ-LPH) are produced by the pars distalis. α-Melanocyte stimulating hormone (α-MSH), β-melanocyte stimulating hormone (β-MSH) and corticotropin-like intermediate lobe peptide (CLIP)[1], however, are thought to be formed in the pars intermedia[2], their being found only in those species in which this structure can be distinguished. They have not been identified in man[3]. The human foetus, however, does develop a rudimentary pars intermedia which involutes shortly after birth[4]. We present, for the first time, evidence for the occurrence of peptides resembling α-MSH and CLIP in the human foetal pituitary in the second half of pregnancy, and we suggest that these peptides are the dominant hormones of foetal life, only replaced by ACTH before parturition.

Human foetal pituitaries were dissected at autopsy following stillbirth, hysterotomy or neonatal death and adult human pituitaries obtained *post mortem*.

Fractionation of an adult pituitary extract on Sephadex G-100 showed two peaks of large molecular weight material reacting in the β-MSH assay and running in the expected positions of β- and γ-LPH (Fig. 2). There was no significant amount of low molecular weight material corresponding to the position of authentic (1–18) β-MSH. A substantial peak of material reacting in both the C- and N-terminal ACTH assays corresponded to intact ACTH, whereas a shoulder on the trailing edge of this peak contained C-terminal activity which could represent a small amount of CLIP. The final small peak of N-terminal activity can probably be attributed to an α-MSH-like peptide; the melanocyte-stimulating potency of this peak was greatly in excess of that in the ACTH peak but not as large as could be expected for authentic α-MSH.

Fractionation of a pituitary extract from a 24-week female foetus from whom the pituitary was dissected within one hour

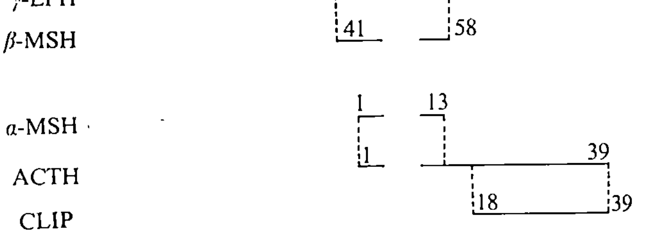

Fig. 1 Corticotropin, lipotropin and melanocyte stimulating hormones. β-LPH is a 91-amino acid peptide whose first 58 amino acids are identical in sequence to γ-LPH. β-MSH shares its 18-amino acid sequence with both β- and γ-LPH. ACTH is a 39-amino acid peptide whose first 13 amino acids are identical in sequence with α-MSH, and whose 18–39 sequence is identical to CLIP. · · ·, The common heptapeptide core responsible for melanocyte stimulating activity in β-LPH, γ-LPH, β-MSH, α-MSH and ACTH.

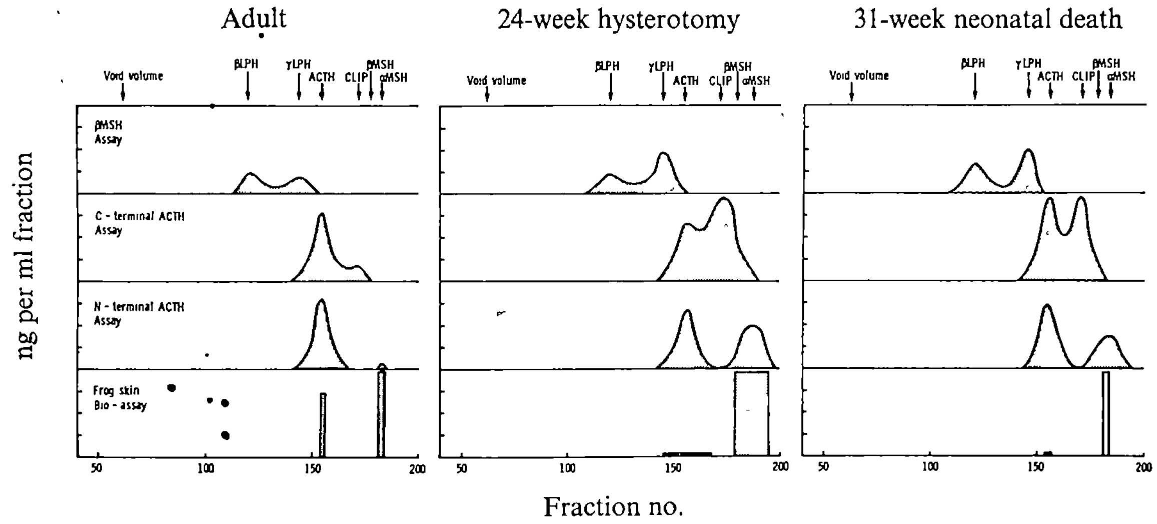

Fig. 2 Chromatography of pituitary extracts on Sephadex G-100. Pituitary fractionations from an adult, a 24-week foetus delivered by hysterotomy and a 31-week infant who survived 12 h post partum. Pituitaries were homogenised in 0.02 M HCl containing 10^{-3} M diisopropylphosphofluoridate. After centrifugation a sample from the supernatant was applied to a column (1.6 × 100 cm) of Sephadex G-100 and eluted in 1 M acetic acid. The fractions were analysed in three systems of radioimmunoassay: a β-MSH assay, a C-terminal ACTH assay and an N-terminal ACTH assay. The β-MSH assay[5] reacted with β-MSH, β-LPH and γ-LPH. The C-terminal ACTH assay[6] reacted with ACTH and CLIP. The N-terminal ACTH assay[7] reacted with ACTH and α-MSH. Selected fractions encompassing the peaks for α-MSH and ACTH were also examined for melanocyte stimulating activity by an adaptation of the frog skin bioassay[8]. In this assay the relative potency of α-MSH to ACTH is 1,000:3. Arrows indicate expected positions of β-LPH, γ-LPH, ACTH, CLIP, β-MSH and α-MSH for each of the chromatograms.

of hysterotomy also showed large molecular weight material reacting in the β-MSH assay representing β- and γ-LPH (Fig. 2). As with the adult there was no evidence of low molecular weight authentic β-MSH. A peak of material reacting in both the C- and N-terminal ACTH assays corresponded to intact ACTH. This, however, was followed by a more substantial peak of material which contained solely C-terminal activity and a significant peak of low molecular weight N-terminal activity. The biological potency of the latter was again far in excess of that which could be accounted for by ACTH.

A pituitary extract from a 31-week male infant who died 12 h after a normal delivery was fractionated and demonstrated a pattern intermediate between that of the adult and that of the 24-week foetus (Fig. 2). The peak of material in the C- and N-terminal ACTH assays which corresponded to intact ACTH was approximately equal to the peak of material with solely C-terminal activity and exceeded the peak of low molecular weight N-terminal activity. This last peak again displayed high biological potency. There were peaks representing β- and γ-LPH as before, but no suggestion of any activity that could represent β-MSH.

Extracts of a further four foetal pituitaries were analysed on a BioGel P6 column which gives a clear distinction between ACTH and CLIP. Two stillborn foetuses at 33 and 38 weeks showed a striking preponderance of C-terminal activity over intact ACTH (Fig. 3). In this they resembled the 24-week foetus delivered by hysterotomy (Fig. 2). The proportion of intact ACTH, however, was much increased in a full-term stillborn foetus and was the dominant hormone in a full-term infant who survived 5 h. In two adult pituitaries (69 and 71 yr) there was a large preponderance of ACTH over material resembling CLIP.

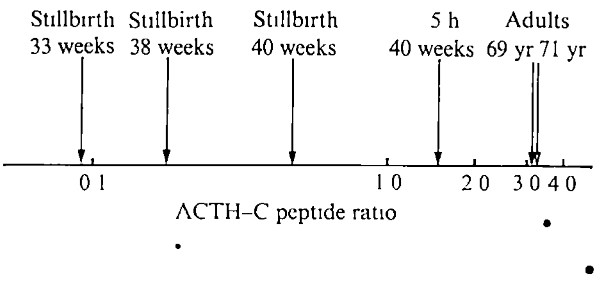
Since the 31-week premature infant who survived 12 h (Fig. 2) resembles the two full-term foetuses rather than those of 33 and 38 weeks, it may be that the changing ratio of the small C-terminal peptide to intact ACTH seen in Fig. 3 is associated with parturition rather than with advancing gestational age.

These studies demonstrate that for the most part of intrauterine life the human foetal pituitary contains only small amounts of intact ACTH, but relatively larger quantities of peptides closely resembling α-MSH and CLIP. It seems probable that the presence of these small molecules reflects a physiological function in the foetus which is not present in postnatal life. It is of interest to consider this finding in the light of other information on the development of pituitary–adrenal function in the human foetus.

The foetal zone of the human adrenal cortex achieves great size during gestation. At parturition it undergoes rapid involution and the definitive zone hypertrophies. It is commonly argued[9,10] that foetal pituitary ACTH is the trophic hormone for both the foetal and definitive zones of the adrenal cortex. ACTH administered exogenously, however, is not itself capable of stimulating the foetal zone[11], and our findings suggest that ACTH is not produced in large quantities by the human foetal pituitary during the major part of gestation. That the trophic hormone responsible for the growth of the foetal zone might be one of the small peptides identified here, for the first time, is an attractive hypothesis. We have demonstrated that near parturition there is a sharp increase of intact ACTH relative to the smaller peptides. If this were reflected in plasma concentrations the metamorphosis of the foetal adrenal gland during this period would be explicable. The transference of function from foetal to definitive zone would accompany the switch in peptide synthesis by the pituitary.

It is the physiological significance of these events, however, which is of most interest. Liggins has demonstrated that the key event preceding parturition in sheep is a surge of foetal cortisol from the foetal adrenal cortex[12]. This event not only helps prepare the foetal lamb for extrauterine existence (for example the production of surfactant in the foetal lung) but it is itself the

Fig. 3 Ratio of ACTH activity to small C-terminal peptide activity in adult and foetal pituitaries as assessed by chromatography on BioGel P6. The foetal pituitaries were obtained from a 33-week stillbirth, a 38-week stillbirth, a 40-week stillbirth and a full-term infant who survived 5 h. Adult pituitaries were obtained *post mortem* from patients aged 69 and 71 yr.



trigger for the initiation of parturition. Premature delivery can in fact be induced at any time in the second half of pregnancy by infusing the foetal lamb with ACTH or cortisol.

It is impossible to determine by direct experiment whether the production of cortisol is of similar significance in the human foetus. Cord blood values for cortisol are, however, greater in babies delivered spontaneously than in those delivered by induction or Caesarean section[13]. It has also been demonstrated that the levels of cortisol in amniotic fluid remain low until week 34 of gestation, but then increase sharply until term[14].

The foetal zone of the human adrenal cortex, though highly active in steroidogenesis, is unable to synthesise glucocorticoids. It is therefore probable that the increased cortisol production derives from the definitive zone. If our hypothesis proves correct that one or other of the small peptides resembling α-MSH and CLIP are the trophic hormones for the foetal zone, while intact ACTH drives the definitive cortex, then the increase of ACTH relative to the small peptides which we have described near parturition would seem to be functionally related to the increasing production of cortisol by the definitive zone of the foetal adrenal gland. Thus the switch in peptide synthesis may be the central mechanism in the chain of events that leads from the passive placenta-dependent foetus to the viable responsive newborn baby.

We thank Drs R. F. Alexander, M. S. Ross, Morag Ellison, Sylvia Lawler, Professor P. Huntingford, Mr A. J. Woolf and the staff of the tissue bank of the Royal Marsden Hospital for the provision of foetal pituitaries, and Dr A. P. Scott for most valuable advice regarding the extraction procedure R.E.S. was supported by the Wellcome Trust and is at present an MRC Research Fellow.

Absolute identification of melatonin in human plasma and cerebrospinal fluid

MELATONIN, the compound responsible for the lightening of amphibian skin, was extracted from bovine pineal glands and chemically characterised by Lerner *et al.*[1,2]. Recent reviews[3–5] have suggested that melatonin has an endocrine role, particularly in relation to chronobiology, pituitary function and cerebral physiology. Most of this work has been accomplished by animal experimentation So far the evidence for the existence of melatonin in man has been indirect. It is formed biosynthetically from tryptophan and the necessary enzyme system is known to be present in the human pineal throughout life[7]. There is however little evidence to suggest that it circulates in human blood or cerebrospinal fluid (CSF). Attempts to identify melatonin by bioassay[8] or radioimmunoassay[9] have not been accompanied by the chemical identification of the substance measured. We present here, for the first time, unequivocal evidence based on gas chromatography (GC) and mass spectrometry (MS) of the presence of melatonin in human plasma and CSF.

Plasmas from normal volunteers and CSF from patients undergoing lumbar puncture as part of other clinical investigations were used. Individual samples were extracted with chloroform. Most lipid and pigment was removed from the chloroform extract by silica gel column or thin-layer chromatography with hexane–ether (80 : 20) as solvent. Melatonin was eluted with methanol and blown to dryness under argon. Using tritiated melatonin, recoveries in excess of 80% were found at this stage.

Synthetic melatonin was treated with a specific silanising reagent (Sylan BTZ, Supelco) to form the indole *N*-trimethylsylil derivative. When a Varian Mat 311A mass spectrometer interfaced to a Varian Aerograph 1400 GC was used, the mass spectrum of this derivative gave rise to two major fragments at mass to charge ratio (m/e) 232 and 245 and a molecular ion at m/e 304 of lower intensity (Fig. 1).

Plasma and CSF extracts were silanised similarly. Pooled plasma extracts (3-ml equivalents) yielded a component with GC retention time and mass spectrum identical with those of synthetic melatonin (Fig. 1) Individual plasma and CSF extracts equivalent to 0.2 ml were subjected to high resolution mass fragmentography at m/e 232 and 245 to give, at the correct GC retention time for melatonin, peaks with accurate mass identical to those of synthetic melatonin.

The elucidation of any physiological or even pathological role for melatonin in man requires first its identification and subsequently its quantification. Our results constitute the first absolute identification of melatonin in human plasma and CSF. Moreover, the major ions 232 and 245, since they carry a large proportion of the total ion current of silanised melatonin, may be utilised in a single ion detection procedure for sensitive quantitative analysis. Thus GCMS in demonstrating the existence of circulating melatonin in man provides at the same time a method for its assay

Protection of spermatogenesis by α_{2u} globulin in rats treated with oestrogen

α_{2u} GLOBULIN is an androgen-dependent rat urinary protein with a molecular weight of about 23,800 (ref. 1). In the male rat, starting from puberty until senescence, α_{2u} globulin is synthesised and secreted by the hepatic tissue and is rapidly cleared by the kidneys into the urine[2–4]. In addition to its urinary concentration α_{2u} globulin has been found to be concentrated by the salivary glands and released into the saliva (A.K.R., and J.G.B., in preparation). Synthesis of this protein could be induced in the spayed female rat by androgen, and oestrogenic compounds completely inhibited α_{2u} synthesis in the mature male rat[5]. But α_{2u} globulin does not bind testosterone, oestradiol-17β or any of their metabolites (unpublished results of A.K.R.). Pretreatment of mature male rats with oestrogen induces a dose-dependent temporary lag period within which α_{2u} globulin is not synthesised even under androgenic stimulation. With a daily oestradiol dose of 50 μg per 100 g body weight a lag period extending up to 3–4 weeks has been established[6]. Although the adult male rat synthesises 20–30 mg of α_{2u} globulin per day, no physiological role of this protein has yet been established. The close parallel between the male reproductive capability and the production of α_{2u} globulin[4,5] prompted us to look into the possible reproductive role of this protein. The discovery of the oestrogen-mediated lag period in the mature male rats also provided an opportunity to look into the spermatogenic abnormalities within this lag period and any reparative effects which α_{2u} globulin may have on such damage. The results reported here demonstrate considerable protection of spermatogenesis by α_{2u} globulin against potential damage by oestrogen.

α_{2u} Globulin was prepared from male rat urine as before[7]. The protein was purified further on a Sephadex G-75 column. α_{2u} Globulin prepared according to the above procedure gave a single electrophoretic band on sodium dodecyl sulphate(SDS)–polyacrylamide gel electrophoresis. Because investigations by Lacy and Lofts[8] have indicated that damage to spermatogenesis caused by oestrogen could be reversed by follicle stimulating hormone (FSH), it was considered important to rule out any possible trace of contamination of FSH in our α_{2u} preparation.

Potent antiserum against FSH-B was prepared by repeated injection of the hormone with Freund's complete adjuvant into rabbits, using a procedure outlined for preparation of antiserum against α_{2u} globulin[7]. The antiserum prepared according to the above procedure, when tested on Goodman plates[9], produced four precipitin lines against 25 μg of FSH-B and three precipitin lines (one major and two minor) with the same amount of FSH-1. Even 100-fold excess of α_{2u} globulin (2.5 mg) showed no precipitin reaction against the antiserum. Double antibody radioimmunoassay[10] of a solution (2.5 mg ml^{-1}) of α_{2u} globulin preparation under various dilutions with the anti-FSH and FSH-1 system also failed to detect any trace contamination of FSH in the α_{2u} preparation. Antiserum prepared against α_{2u} globulin also yielded no precipitin reaction when tested against whole pituitary homogenate.

Mature male rats of Yale strain (about 100 d old at the start of the experiments) were used for this investigation. Thirty-five animals were treated daily with oestradiol-17β for 7 d (50 μg per 100 g body weight per d). At the end of treatment, five animals were killed and their testes were fixed in Bouin's fixative and used for paraffin embedding. The remaining 30 animals were divided into two groups, one of which received injections of 0.2 ml of 0.14 M NaCl per day and the other received subcutaneous injections of α_{2u} globulin (1 mg in 0.2 ml of 0.14 M NaCl per animal per day) for the rest of the experimental period. Five animals from each group were killed at 7-d intervals and their testicular tissue was fixed in Bouin's fixative and used for

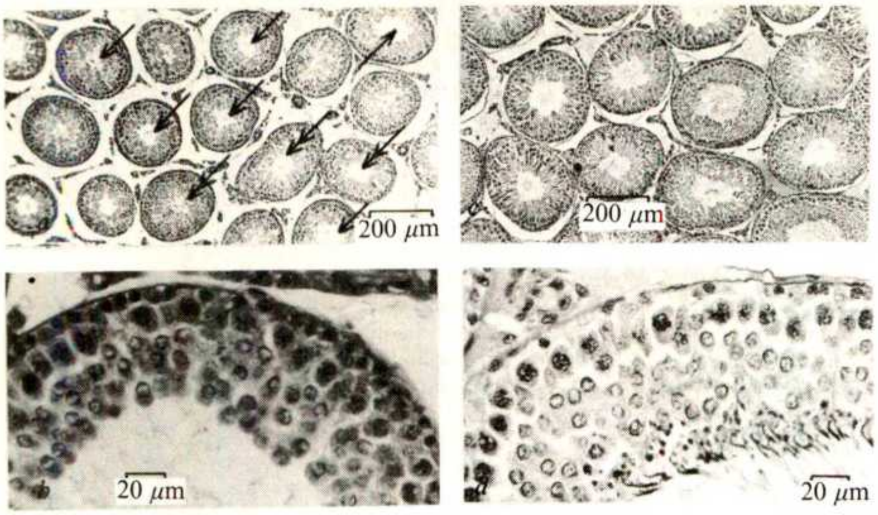

Fig. 1 Photomicrographs of PAS–haematoxylin-stained sections of the testes from animals treated with oestrogen alone and with oestrogen followed by α_{2u} globulin. *a*, Testicular sections from control animals receiving daily injections of oestradiol-17β for the first 7 d followed by injections of 0.2 ml of 0.14 M NaCl (placebo) per day for the next 3 weeks. Tubules marked with → show absence of step 15 to step 19 spermatids. Tubules marked with →→ show drastic reduction of step 9 to step 14 spermatids. Considerable shrinkage of the tubular diameter could also be noted when compared with (*c*). *b*, Treatment same as for (*a*). This photomicrograph shows the cross section of a tubule at stage VIII of the seminiferous cycle. Note the absence of step 19 spermatids. *c*, Testicular section from an animal treated daily with oestradiol-17β for the first 7 d, followed by daily treatment with α_{2u} globulin for the next 3 weeks. The tubular sections show normal spermatogenesis with normal cellular associations at various stages of the cycle. Unlike the section shown in (*a*), no tubular shrinkage could be seen. *d*, Treatments same as for (*c*). This photomicrograph shows the cross section of a tubule at stage VIII of the seminiferous cycle. In contrast to (*b*) the tubule shows normal spermatogenesis proceeding up to mature step 19 spermatid.

paraffin embedding. Sections (5 μm thick) of the testes were stained with periodic acid–Schiff (PAS)–haematoxylin and used for histological evaluation[11,12].

The stained sections from animals treated for 7 d with oestradiol-17β and killed on the eighth day showed no discernible change in spermatogenesis. Testicular sections from animals treated for 7 d with oestradiol and another week of rest period (no hormone treatment) also showed almost normal morphology. Tubular shrinkage and degenerative changes were found to appear at the second week after the last oestradiol treatment. Seminiferous epithelium in these groups of animals (2 weeks after last oestradiol treatment) showed drastic reduction and in some sections complete absence of spermatids of step 9 to step 19. Some of the pachytene spermatocytes within stages VIII through XIII also showed degenerative changes. The testicular sections from animals killed 3 weeks after the last oestradiol treatment showed relatively small and atrophic tubules. Qualitatively, spermatogenesis was found to progress only up to step 7–8 spermatids. Step 9–19 spermatids were found to be absent in most of the tubules and in some instances when present were invariably abnormal (Fig. 1*a* and *b*). Quantitative evaluation of the abnormality within the various stages of the seminiferous cycle are summarised in Table 1.

Table 1 Quantitative evaluation of the oestrogenic damage and its prevention by α_{2u} globulin of the seminiferous epithelium at various stages of the spermatogenic cycle

Cellular associations (stages of the cycle)	Index of degeneration in group 1 (oestrogen alone)			Index of degeneration in group 2 (oestrogen followed by α_{2u} globulin)		
	Day 14	Day 21	Day 28	Day 14	Day 21	Day 28
I	0	80	72	0	0	0
II	0	25	58	0	0	0
III	0	62	73	0	0	0
IV	0	66	100	0	0	0
V	0	55	90	0	0	0
VI	6	42	93	0	0	0
VII	7	82	100	0	0	0
VIII	0	50	100	0	0	0
IX	8	83	19	0	0	0
X	0	83	11	0	0	0
XI	0	54	16	0	0	0
XII	4	72	42	0	0	0
XIII	0	72	42	0	0	0
XIV	0	40	31	0	0	0

All animals were treated for the first 7 d with oestradiol-17β (50 μg in 0.1 ml vehicle per 100 g body weight per day; subcutaneous injection of the hormone as an emulsion in 0.1 M sodium phosphate, *p*H 7.2, propylene glycol and Tween 80, 89.6:10.0:0.4, by volume). After initial oestrogen treatment, the animals in group 1 received no other treatment except daily injections of 0.2 ml of saline (0.14 M NaCl). Beginning from the 8th day (1 d after the last oestrogen injection) until death, the animals in group 2 received daily injections of α_{2u} globulin (1 mg per rat per d, subcutaneously in 0.14 M NaCl). The tubular cross sections showing the presence of degenerating germinal cells and/or containing less than 50% of any particular cell type within the specific cellular association were considered to be abnormal. Percentage tubular cross section showing abnormality is used as the index of degeneration.

$$\text{Index of degeneration} = \frac{\text{No. of abnormal tubular cross sections}}{\text{Total no. of tubular cross sections examined}} \times 100$$

The fractional numbers are brought to the nearest whole number.

The group of animals given daily injections of α_{2u} globulin after initial treatment with oestradiol-17β showed no degenerative changes in their testicular sections throughout the period of investigation. The testicular sections from this group of animals 1, 2 and 3 weeks after the last oestradiol treatment showed an intact seminiferous cycle leading to normal spermatogenesis (Fig. 1*c* and *d*; Table 1).

In another series of experiments, adult male rats after the first 7 d of oestrogen treatment were subsequently treated with testosterone alone (250 μg per 100 g body weight) and testosterone plus α_{2u} globulin. Although testosterone, together with α_{2u} globulin, could provide complete protection against the oestrogen-induced damage to spermatogenesis, testosterone alone failed to do so.

The results presented here show that α_{2u} globulin can provide protection against oestrogen-mediated damage of spermatogenesis in the rat. We have shown before that oestrogen treatment completely stops the synthesis of α_{2u} globulin within 7 d, and with a dose of 50 μg per 100 g body weight reinitiation of α_{2u} synthesis does not start until 3–4 weeks later[6]. Therefore, any possible spermatotropic role of α_{2u} globulin is expected to be missing within the oestrogen-mediated lag period. The observed damage to spermatogenesis, in particular the failure of spermatid maturation in the oestrogen-treated group, and the prevention of such inhibitory effect by α_{2u} globulin within the lag period, may indicate a physiological role of α_{2u} globulin in spermatogenesis.

We thank Dr V. N. Reddy, Dr N. J. Unakar and Marian Wilson for criticisms and suggestions. Rat FSH and anti-FSH preparations were given by the NIAMDD rat pituitary hormone distribution program of the National Institute of

Arthritis, Metabolism and Digestive Diseases. This work was supported by a grant from the National Institutes of Health

Biochemical responses in lungs of ozone-tolerant rats

THE health hazard of ozone, the principal oxidant air pollutant of photochemical smog, has been well documented[1–3]. One of the notable features of ozone toxicity is the development of tolerance. When animals are exposed to a single sublethal dose of ozone they become resistant to subsequent lethal exposure. This tolerance phenomenon has been demonstrated in several species, and the effect has been shown to persist for well over one month[3–8]. One of its toxic effects has been attributed to its oxidative nature, and, more specifically, the initiation of lipid peroxidation[7–9]. Glutathione peroxidase (GP), which uses the reducing equivalent of reduced glutathione (GSH) to catalyse the decomposition of toxic hydroperoxides, and metabolically related enzymes glutathione reductase (GR) and glucose-6-phosphate dehydrogenase (G6PD), have been suggested as a key mechanism for protection of cellular components from deleterious effects of hydroperoxides[10,11]. The activities of these enzymes have been found to increase in the lungs of rats exposed to chronic levels of ozone[9], and in tissues of rats subjected to other oxidative stress[12,13] Thus changes in the activities of these enzymes seem to be related in some way to the defence mechanism against peroxidative damage. In this study, rats tolerant to ozone maintained higher activities of GP, GR and G6PD, and higher levels of GSH in the lungs following excessive exposure. The adaptive response of this potentially protective enzymic system in the lungs of ozone-tolerant rats may therefore be partly responsible for their resistance against lethal exposure.

Seventy-day-old male Sprague–Dawley rats (chronic respiratory disease free) were initially exposed to either 0 or 0.76 p.p m. ozone for 3 d (to develop tolerance) in monitored chambers as described previously[9]. After 8 d of recovery in an air-filtered room, portions of tolerant and non-tolerant animals were exposed to either 0 or 4.0 p.p.m. ozone for 8 h Sixteen hours later surviving animals and their respective controls were killed by exsanguination following pentobarbital injection. After perfusing with saline through the pulmonary artery to remove blood, the lungs were homogenised, fractionated and assayed for the activities of GP, GR, G6PD, and levels of protein and GSH as described previously[9,14]

Sixteen hours after the end of the acute exposure, five out of ten non-tolerant rats died compared with only one out of seven of the tolerant group. The lungs of both acute exposed groups exhibited severe haemorrhage and oedema, but the tolerant animals showed less severe injury. The biochemical responses of the lungs are summarised in Table 1. Exposure of rats to 4.0 p.p.m. ozone for 8 h resulted in a marked increase in protein content, and a significant ($P<0.05$) decrease in the activity of GP, GR and G6PD, and levels of GSH in the lungs of both tolerant and non-tolerant groups. Tolerant animals, however, showed significant, higher activities (from Student's *t* test) of GP, GR and G6PD, and higher GSH levels in the lungs than

Table 1 Biochemical responses in the lungs of rats exposed to ozone 16 h after the end of exposure to 4 p.p.m. ozone for 8 h

Biochemical parameter	Tolerance*	Exposed (mean ± s.d.)	Control	*P*
Protein (mg per lung)	Yes	136 ± 6	71 ± 4	<0.001

*Exposed to 0.76 p.p.m. ozone for 3 d and allowed to recover for 9 d. NS, Not significant ($P \geq 0.05$).

those of the non-tolerant rats. When the data are expressed as total units per lung, tolerant rats still show a higher level of GSH and higher activities of GP, GR and G6PD. It should be noted that the above biochemical parameters in the lungs of rats recovering for 9 d from the initial exposure were not different from those of the non-exposed controls (Table 1)

In another experiment, 60-d-old male rats were initially exposed to either 0 or 0.73 p.p m. ozone for 3 d. Eleven days after exposure, 11 tolerant and 13 non-tolerant animals were exposed to 3.9 p.p.m. ozone for 8 h Only one of the tolerant rats had died 18 h later, as against seven of the non-tolerant group. The lungs of tolerant animals also showed relatively less severe injury and maintained higher activities of GP, GR and G6PD, and higher GSH levels.

Throughout this research, it was observed that the activities of GP, GR and G6PD, and GSH levels in the lungs of animals exposed to 0 8 p.p.m. ozone for 3 d increased significantly above those of the controls, and that these biochemical changes began to revert towards control values in 2 d, reaching control levels about 7 d after recovering in ozone-free air (unpublished observations). Even though the biochemical changes in the lungs of tolerant rats completely returned to control level, significantly higher activities of GP, GR and G6PD, and GSH levels, accompanied by a reduced mortality rate and lung injury were developed when this group of rats were subjected later to the acute exposure. Although the precise significance and specificity of this correlation remain to be seen, it is possible that higher activities of GP, GR and G6PD, and GSH levels in the lungs of tolerant animals may render them more resistant to peroxidation damage induced by ozone. It has been shown that ozone-tolerant animals maintained higher GSH levels in the lungs, and theorised that the activities of pentose shunt pathway may be related to resistance or tolerance to injury from inhaled irritants[4,15].

The mechanisms of the differential biochemical response between the tolerant and non-tolerant rats to acute ozone exposure remain to be elucidated. It is possible that the enzymic synthesis machinery in the lungs of tolerant rats remained 'potentially active' even though the enzyme activities reverted to control levels. It has been shown morphologically that ozone primarily affects the type 1 cells of small conducting airways and adjacent alveoli[16,17]. Following injury to less than 1 p p m. ozone, repair processes, as evidenced by the replacement of type 1 cells by the cuboidal epithelial cells in the injured areas, begin within 24 h and reach a maximum between 48 and 72 h When animals are allowed to recover in room air, the cuboidal cells are gradually transformed into type 1 cells, and the tissue returns to normal in about 7 d (refs 16 and 18) From a morphological point of view, therefore, the newly transformed type 1 cells may be potentially more prone to metabolic change and thus become more resistant to subsequent exposure. Further studies such as morphometric measurement of type 1 and type 2 cells are, however, needed to clarify this view.

The GP system also has an important role in protecting red blood cells against oxidative damage. When red cells genetically lack one or more of these enzymes or enzymes involved in GSH synthesis, they become susceptible to oxidative drugs which induce haemolytic anaemia[19,20] The GP system may also be involved in tolerance phenomena induced by other types of oxidative agents, as GP uses a variety of hydroperoxides as substrates[10].

The present observations that tolerant animals are capable of maintaining higher activities of GP, GR and G6PD, and GSH levels in the lungs suggest that this enzymic system may be partly responsible for their resistance against lethal ozone exposure This study provides evidence for the possible role of the protective GP system in the development of tolerance to oxidative damage.

Mutagenic action of ascorbic acid

MICROBIAL[1], mammalian[2,3] and human[4,5] bioassays are being applied to uncover the mutagenic action of synthetic compounds which have been introduced accidently or intentionally into the environment Somewhat less attention has been given to the potential genetic hazard of chemicals which are an essential part of human nutrition or are formed within mammalian tissues and organs. Ascorbic acid belongs to this group of "neglected" naturally occurring compounds, although its capacity to form radicals and its interaction with viral[6] and bacterial[7] DNA should have raised suspicion about its possible mutagenic capacity. Considering the large daily intake of ascorbic acid, its addition to many food products[8] and its potential use as an inhibitor of the intragastric formation of *N*-nitroso compounds[8,9] and nitrosamine formation in food products[10], its action on the genome of human cells requires investigation. We here present evidence, from several experimental systems, suggesting that vitamin C, particularly in the presence of copper, has a mutagenic effect.

Several endpoints were used to uncover the effect of freshly prepared ascorbic acid and an ascorbic acid–Cu^{2+} mixture on the genome of cultured human fibroblasts. DNA fragmentation was measured as a shift in sedimentation profile after centrifugation in an alkaline sucrose gradient[11], DNA repair was estimated as unscheduled uptake of tritiated thymidine (^3H-TdR) into non-dividing cell populations[13] and chromosome aberrations were quantified by counting breaks and exchanges on the first metaphase plate after treatment Fibroblasts were obtained from small skin biopsies of four healthy 20–26-yr-old females and males and were used at the third to fifth tissue culture passage. The mutagenic capacity of ascorbic acid and an ascorbic acid–Cu^{2+} mixture were tested further using Ames' tester strain TA 100 of *Salmonella typhimurium*[1].

Cultured human fibroblasts treated with a mixture of ascorbic acid (Mallinckrodt) and Cu^{3+} exhibited DNA fragmentation (Fig. 1), DNA repair synthesis (Fig 2), and chromosome aberrations including chromatid breaks and exchanges (Table 1). An application of $CuSO_4$ at concentrations varying from 10^{-6} to 10^{-4} M had no detectable effect

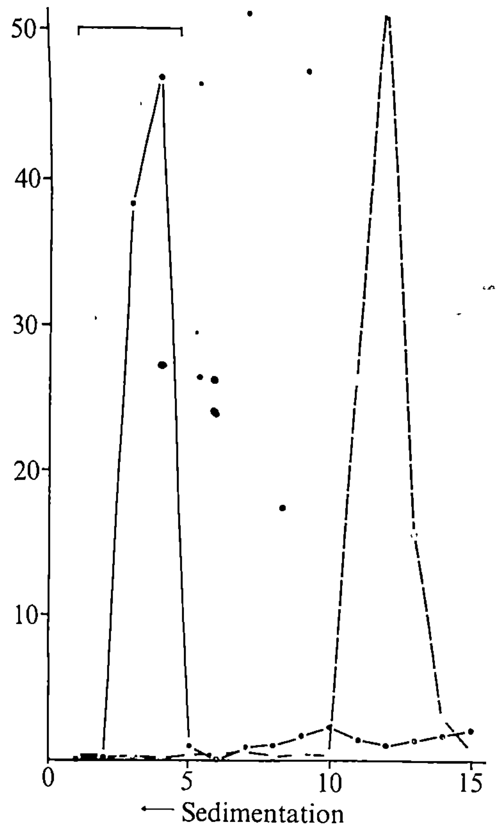

Fig. 1 Alkaline gradient sedimentation profiles of ^{3}H-DNA released from cultured human fibroblasts. ●, Cells exposed for 2 h to 1.8×10^{-5}M $CuSO_4$; ○, cells exposed for 2 h concurrently to ascorbic acid (1.8×10^{-3}M) and $CuSO_4$ (1.8×10^{-5}M). Horizontal bar indicates the sedimentation range into which DNA from untreated fibroblasts falls ^{3}H-TdR (1 µCi ml^{-1}) was added to the replicating fibroblasts for 20 h; thereafter the cell cultures were exposed to the compounds, rinsed four times with cold 0.024 M EDTA/0.075 M NaCl buffer (pH 7 5), scraped from the Petri dish surface, pelleted (3 min, 1,000 r p.m.), resuspended to give 10^4–10^6 cells per 100 µl, and placed on a lysing solution[11] on top of a linear alkaline sucrose gradient (5–20%, 5 ml) which was prepared over a 1-ml cushion of 2.3 M sucrose. After a 10-min lysis period at 25 °C the gradients were centrifuged at 25,000 r.p.m. for 30 min.

Table 1 Metaphase plates of cultured human fibroblasts with chromosome aberrations (breaks and exchanges) after a 2-h exposure to oxidised ascorbic acid and an ascorbic acid $CuSO_4$ mixture

	Metaphase plates with chromosome aberrations (%)*	
	Ascorbic acid+O_2†	Ascorbic acid+Cu^{2+}‡
2×10^{-3} M	25.8	—§
1×10^{-3}	28.5	—
6×10^{-4}	23.4	—
3×10^{-4}	15.0	26.5
1.5×10^{-4}	5.0	5.4
Controls	0–15	

Controls were cultured cells untreated with the ascorbic acid preparations.

*Samples were taken 18 h after treatment and 4 h after application of colchicine.

†O_2 was flushed through the ascorbic acid solution for 2 h before addition to the cultured fibroblasts.

‡The ascorbic acid–$CuSO_4$ ratio was 1,000:1

§Concentrations of 6×10^{-4}M and greater suppressed cell division.

Table 2 Frequency of mutations (*his*$^+$ revertants) of *S. typhimurium* (TA 100) after exposure to ascorbic acid, ascorbic acid plus Cu^{2+} or MNNG

	his$^+$ Reverents per 10^6 survivors*		
	Ascorbic acid	Ascorbic acid+Cu^{2+}	MNNG
3.5×10^{-2}M	2.2	160.0	—
2.5×10^{-2}	1.4	108.7	3,090.9
1.5×10^{-2}	0.7	3.8	—
1.0×10^{-2}	1.6	1.2	—
5.0×10^{-3}	1.1	1.0	171.4
Control†	1.1 (0.5–2.1)	—	—

*Bacteria in suspension were treated with the various compounds for 15 min at 22 °C, washed, centrifuged, resuspended with nutrient broth and plated on histidine-deficient culture medium[1]. The ascorbic acid+$CuSO_4\times5H_2O$ (1,000:1) solution was incubated for 30 min at 37 °C before use

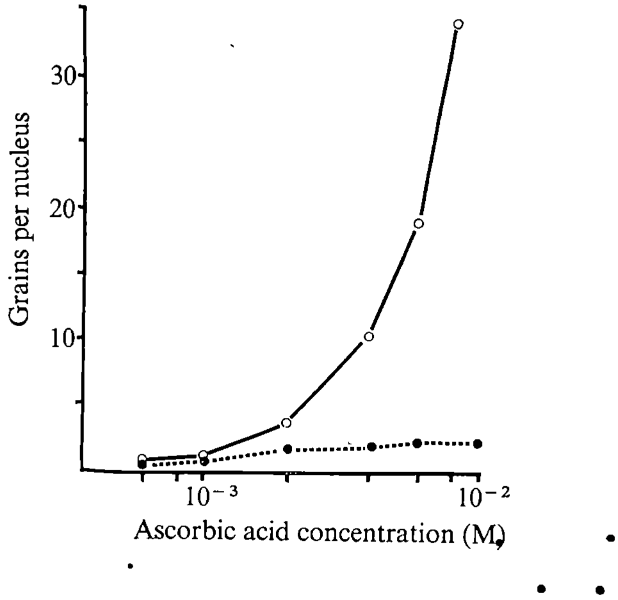
†Controls were bacteria untreated with the various chemical preparations. The range of mutation frequencies is shown in parentheses.

on DNA and chromosomes. If the ascorbic acid solution is flushed with N_2 immediately before addition to cell cultures, the DNA-damaging and chromosome-breaking action is virtually abolished The active concentrations of ascorbic acid–Cu^{2+} are relatively high as compared with those of the potent carcinogen and mutagen *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG) which triggers a DNA repair synthesis at concentrations varying from 10^{-7} to 2×10^{-4} M (ref 5), and induces chromosome aberrations at doses of 5×10^{-6} to 6×10^{-5} M (ref 13), or 4-nitroquinoline-1-oxide (4NQO) which starts to elicit these two phenomena at 2×10^{-7} M and 4×10^{-4} M, respectively[5,14].

A significant frequency of *his*$^+$ revertants per surviving bacterial population was induced by a short (15 min) exposure to the ascorbic acid–Cu^{2+} mixture (Table 2). At equimolar concentrations freshly prepared ascorbic acid does not exert a detectable mutagenic effect. The range of the active concentrations of the ascorbic acid–Cu^{2+} mixture is relatively narrow and thus can be missed easily. For comparison, the mutagenic effect of MNNG at these relatively high concentrations has been added to Table 2. In this connection it should be noted that about 100 new *his*$^+$ revertants which require a dose of about 2×10^{-2} M ascorbic acid–Cu^{2+} are induced by as low a concentration of MNNG as 10^{-4} M Copper ions at the concentrations of 10^{-5}–10^{-6} that we used had no detectable effect on the mutation frequency of *S. typhimurium* The latter observation agrees with the lack of mutagenic activity of CuCl and $CuCl_2$ in the rec assay of *Bacillus subtilis*[15].

Considerable evidence has been accumulated to show that oxidation products of ascorbic acid are mutagenic for

Fig. 2 Unscheduled incorporation of ^{3}H-TdR into nuclei of non-proliferating cultured human fibroblasts exposed for 90 min to ascorbic acid: $CuSO_4$ mixtures (○) or an ascorbic acid solution which was bubbled with pure N_2 (Canada Liquid Air Ltd) for 1 h before application to the culture cells (●). The autoradiographic analysis of the incorporated ^{3}H-TdR and the arrest of proliferation by an arginine-deficient culture medium were described before[12]



microbial and mammalian cells: ascorbic acid in the presence of oxygen converts covalently-closed circular DNA to open circular DNA molecules (unpublished results of A. R Morgan, R. C Cone and T M. Elgert), causes single-strand breaks in DNA[6], inactivates transforming DNA of *Pneumococcus*[7], degrades RNA of bacteriophage R17 (ref. 16), induces reverse mutations in *S. typhimurium* (Table 2), fragments DNA of cultured human cells (Fig. 1) and mouse sarcoma cells[17], triggers a DNA repair synthesis (Fig. 2) and elicits chromosome breaks and exchanges (Table 1), as do most, if not all chemical mutagens The precise molecular nature of the ultimate mutagenic metabolite of ascorbic acid is unknown. Whether hydroxyl radicals that are generated in the interaction of Cu$^+$ with H_2O_2, which is in turn produced by the oxidation–reduction activity of the ascorbic acid–dehydroascorbic acid system[18], are responsible for the observed DNA fragmentation and the genetic changes is difficult to assess at present.

It is also difficult to evaluate the degree of genetic hazard posed by vitamin C, its decomposition products, and its interaction with metal ions to man. The effective dose of ascorbic acid in the presence of oxygen or cupric ions varies from 5×10^{-5} M for single-strand scissions of DNA[6] and cleavage of PM2 DNA (unpublished results of A. R. Morgan *et al.*) to between 1 and 8×10^{-4} M for the induction of DNA lesions and chromosome aberrations in cultured human fibroblasts Several potent mutagens, including MNNG, MMS and EMS require also high concentrations to trigger a DNA repair synthesis[4,5]. Thus, the active dose of ascorbic acid products is only two- to tenfold greater than that of potent mutagens if mammalian cells are considered. In the microbial test system, however, ascorbic acid–Cu^{2+} was only weakly mutagenic as compared with MNNG. A too simple application of these *in vitro* data to man can lead to erroneous conclusions. Catalyses may inhibit ascorbic acid-initiated DNA cleavage within the human body. Metabolic products of ascorbic acid may reach the intranuclear DNA molecules only if present in excessive amounts. The ascorbic acid–metal mixtures may have no effect because of the lack of free cupric or ferric ions within cells. Nevertheless, the potential mutagenic capacity of ascorbic acid products should be taken into consideration when a potential health hazard due to the addition of relatively large quantities of vitamin C to food products which contain nitrosatable compounds is evaluated.

Conformational differences in bacterial ribosomal RNAs in non-denaturing conditions

THE conservative nature of bacterial ribosomal RNA (rRNA) is clear from the narrow range of its guanosine–cytosine (GC) content compared with the base composition of whole cell DNA. The majority of bacterial DNAs contain from 35 to 75% GC, whereas the GC content of rRNA is restricted to a narrow range of 50–53% (ref. 1). Indeed, the ribosomal DNA (rDNA) of many bacterial species can be isolated from sheared preparations of whole cell DNA solely on the basis of its GC content. Furthermore, nucleic acid hybridisation has indicated considerable homology between the rRNAs of diverse bacterial species[2-4] and helped provide phylogenetic support for taxonomic relationships. In an investigation of 22 different bacteria Pace and Campbell found that organisms whose rRNA showed closer homology to *Escherichia coli* rRNA, showed less rRNA homology to *Bacillus stearothermophilus* rRNA and vice versa[2]. Both sedimentation and gel electrophoresis studies in non-denaturing conditions have shown very small, if any, migratory differences between either the 23S or 16S rRNA species of different bacterial species[5,6]. By using a modified buffer system coupled with double labelling, we have found that both the large and small species of rRNA from *Streptococcus faecalis*, *B. subtilis*, and *E. coli* can be all distinguished on the basis of significant differences in their mobility in both composite polyacrylamide–Agarose gels and polyacrylamide gels.

The relevant bacterial species were labelled with ^{3}H-5-uridine or ^{14}C-2-uridine and the rRNA was extracted and electrophoresed in composite polyacrylamide–Agarose gels as described in the legend to Fig. 1.

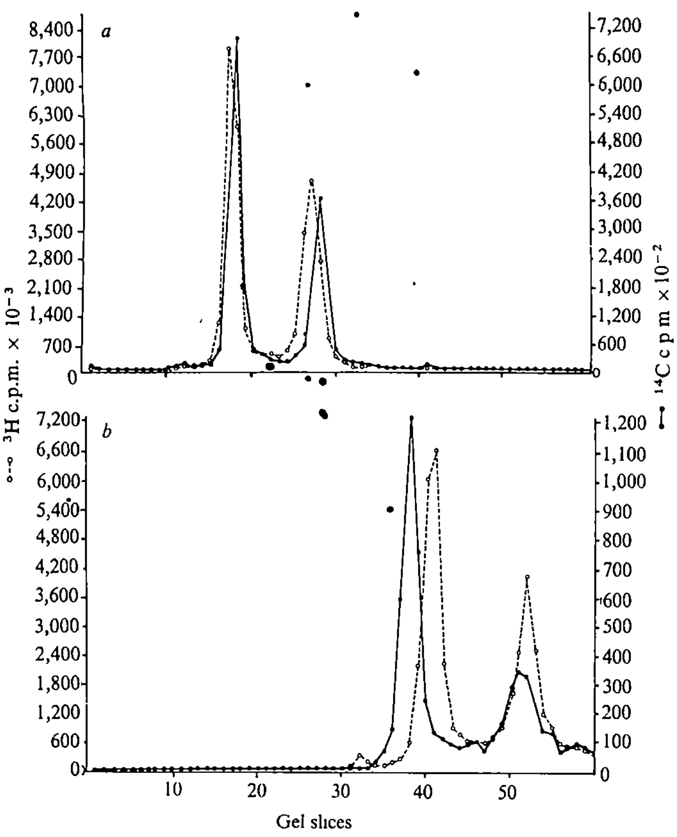
Figure 1*a* shows the clear separation of both 23S and 16S peaks of the rRNAs from *S. faecalis* and *E coli*. Similarly, good separation was achieved between *S. faecalis* and *B. subtilis* (Fig. 1*b*), and *E. coli* and *B. subtilis* (Fig. 1*c*). The 23S and 16S peaks of all species were clearly separated by one or more gel slices. It is not possible to make comparisons between different gels, since the buffer temperature was not controlled during electrophoresis and the runs were made on different days. It is important to note that these differences would not be observable if absorbance measurements were used and thus would be overlooked in electrophoretic studies using unlabelled rRNA.

These migratory differences were confirmed by electrophoresis in similar conditions in 3% polyacrylamide gels. The only exception to the migratory patterns seen in composite gels was that the 16S peaks of *E. coli* and *B. subtilis* coelectrophoresed (Fig. 2).

Electrophoresis of these rRNA species was also carried out in composite polyacrylamide–Agarose gels with a standard internal buffer concentration of 1E which is commonly used in RNA electrophoresis[6]. In these conditions, all the bacterial rRNAs coelectrophoresed with the exception of *B. subtilis* 23S rRNA, which migrated slightly behind the *S. faecalis* and *E. coli* 23S RNA peaks (Fig. 3).

If these migratory differences were to be interpreted according to the method of Loening[6], where distance migrated is inversely proportional to the logarithmic value of the molecular weight, they would be equivalent to 10% differences in molecular weight. Electrophoretic migration in non-denaturing conditions has, however, been shown to be primarily dependent on conformation based on the partially double-stranded nature of single-stranded RNA in aqueous solution. Temperature, ionic strength, *p*H, base sequence and base composition of RNA all seem to be factors which determine conformation.

A common buffer used for electrophoresis of RNA is the 1E buffer of Loening, which is at a physiological *p*H and sodium ion concentration. The *p*H and ion concentration assure that at room temperature the rRNA in gels assumes a conformation similar or identical to its native conformation. Successful



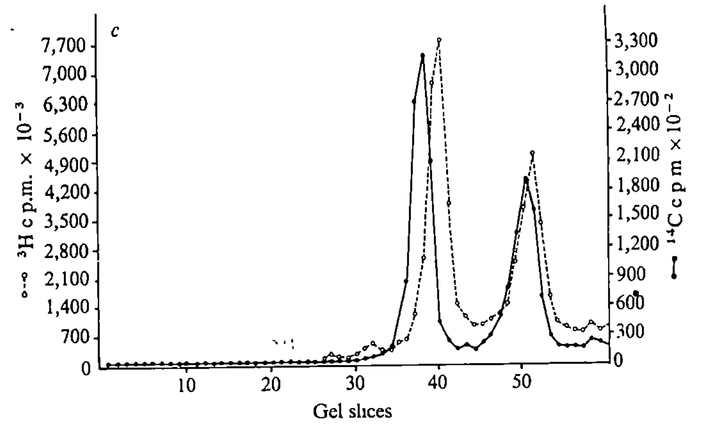


Fig. 1 Bacteria were labelled for 6–12 h of logarithmic growth with either ^{3}H-5-uridine or ^{14}C-2-uridine (Schwartz–Mann) to facilitate uniform labelling of mature rRNA. RNA was extracted with phenol at 40 °C with sodium dodecyl sulphate (SDS)[11]. All the Gram-positive bacteria were treated before extraction with 0.3% lysozyme for 15 min at 45 °C which partially digested the cell wall. RNA was precipitated from the final aqueous phase by addition of cold 0.8 M NaCl and absolute ethanol at −20 °C. After incubation overnight at −20 °C the mixture was centrifuged and the pellet resuspended in 3 M sodium acetate and 5 mM EDTA to selectively precipitate RNA and remove residual DNA. This solution was centrifuged and the pellet resuspended in a small volume of E buffer plus 0.5% SDS and stored at −70 °C (ref. 6). RNA concentration was measured by orcinol determination[12]. Generally, 5 µg of each RNA sample in 5–10 µl of E buffer plus 0.5% SDS were added to each gel. RNA samples to be analysed were mixed and placed on the same gel. Preliminary experiments had indicated that the electrophoretic profiles of rRNAs obtained by coextraction did not differ from those obtained by mixing just before the gel run. Polyacrylamide–Agarose gels were prepared by the method of Peacock and Dingman[13] with the following modifications. The buffer used in gel preparations was 3E rather than 9E so that the final buffer concentration in the gels was 1/3 E rather than 1E[13]. The gels were 2.6% acrylamide, 9–10 cm long and 0.5 cm in diameter. The procedure for gel electrophoresis was that of Loening[6]. The samples were electrophoresed for 1.5 h at 5 mA per gel. In all graphs the direction of electrophoretic migration is from left to right. Because we were interested only in the relative migration of the RNA samples, unwanted sections of the gel were removed from both the top and bottom of the gel. The gel slices referred to on the abscissa therefore do not reflect total distance migrated. After completion of the electrophoretic run the gels were fixed in 1M acetic acid for 15 min, washed with water for at least 30 min, frozen and sliced with a gel slicer (9 slices cm^{-1}). Each slice was placed in a vial with scintillation fluid (PPO–POPOP)+5% protosol tissue solubiliser, prewarmed to 37 °C, and shaken overnight at 37 °C. Vials were counted in a Packard TriCarb Liquid Scintillation Spectrometer Model 3003 *a*, *S. faecalis*, ----; *E. coli*, ——. *b*, *B. subtilis*, ----; *S. faecalis*, ——. *c*, *B. subtilis*, ----; *E. coli*, ——.

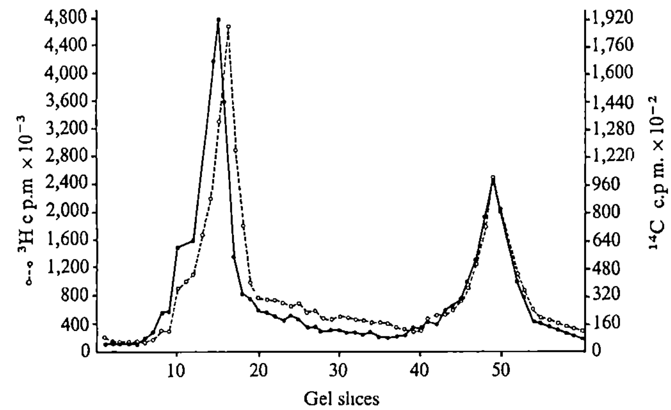

Fig. 2 3% Acrylamide gels were prepared using the monomer mix (acrylamide-*bis*-acrylamide) of the composite gels. Again, the final concentration of buffer in the gels was 1/3 E. The gels were 14 cm long and 0.6 cm in diameter. Electrophoresis was at 10 mA per gel for 2.5 h. *B. subtilis*, ----; *E. coli*, ——.

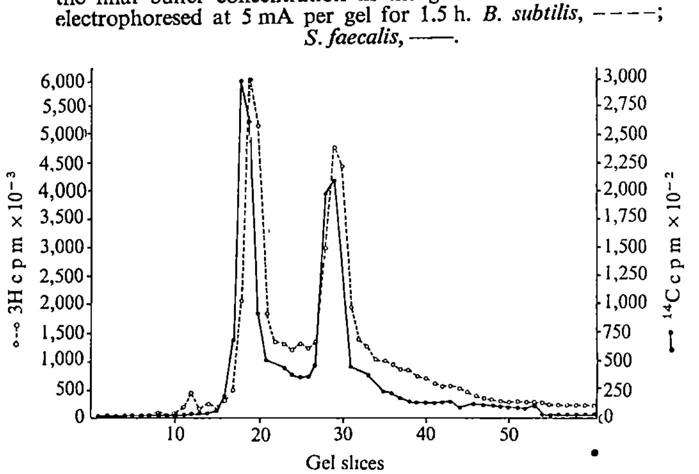
ribosomal reconstitution experiments carried out in similar buffer conditions with homologous rRNA and ribosomal proteins suggests that the rRNA is in a conformation resembling its native state[7]. Successful ribosomal reconstitutions are possible using heterologous rRNA and ribosomal proteins, indicating that the native conformations of rRNAs of different bacterial species have been conserved[7]. It is, therefore, not surprising that bacterial rRNAs coelectrophorese in 1E buffer gels.

The differences in migration of both 23S and 16S rRNA seen in Figs 1 and 2 can be attributed to the use of a 1/3E buffer within gels. The lower sodium ion concentration of this buffer may no longer be able to stabilise the secondary and tertiary interactions of segments of the rRNA, thus leading to partial denaturation. The extent of denaturation is probably determined by the GC content of the double-stranded loops and their base

Fig. 3 Composite polyacrylamide–Agarose gels were prepared as in Fig. 1, except the buffer used in gel preparation was 9E, so the final buffer concentration in the gels was 1E. Gels were electrophoresed at 5 mA per gel for 1.5 h. *B. subtilis*, ----; *S. faecalis*, ——.



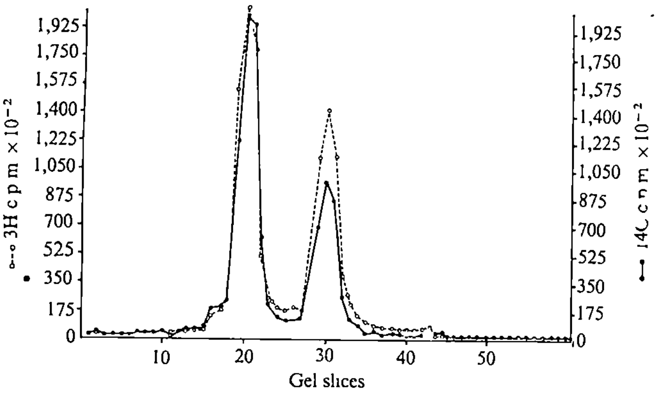


Fig. 4 Formamide gels were prepared according to the method of Staynov *et al.*[14]. All other details of the electrophoretic procedures are the same as described in Fig. 1 except the E buffer used in the electrophoresis chambers was adjusted to *p*H 9.0 rather than 7.8. *B. subtilis*, ----; *E. coli*, ——.

sequence. Therefore, rRNAs with a higher GC content presumably retain more stable double-stranded loops, pack tighter, and behave as smaller (lighter) particles during electrophoresis or sedimentation.

We believe that the electrophoretic differences we observed in the 1/3E buffer may be due to small differences in the GC content of the rRNAs of these particular bacterial species. Determinations of their respective GC contents are in progress.

Owing to the extended length of the labelling period, we do not believe any of the species of rRNA described are precursor RNAs. Morris and Schuap have separately reported multiple conformational forms of both 23S and 16S rRNAs from *E. coli*[8,9]. These forms were only seen, however, when special conditions such as a *p*H gradient[8] or electrophoresis for 7.5 h at 0 °C (ref. 9) were used. We have not seen any multiple peaks in our electrophoresis conditions.

To test our assumption that the differences we observe in non-denaturing gels were due primarily to conformational difference, we ran the rRNA samples on formamide gels. Formamide essentially destroys all secondary bonding and reduces migration to a dependency on the primary polynucleotide sequence[10]. In all cases we found coelectrophoresis of the different bacterial rRNAs. A single example is shown in Fig. 4. Thus, no molecular weight differences were seen between the respective 23S and 16S rRNA of the different bacterial species studied.

Using a combination of lowered ionic strength in our gels and double labelling of rRNAs we were able to show major migrational differences in the electrophoretic mobility of non-denatured rRNA from various bacterial species. Extension of this work could lead to differential rRNA profiles of bacteria; which might be useful in the identification of non-cultivable pathogens, or to help establish phylogenetic relationships between different bacterial species.

This work was supported by grants from the US National Institutes of Health. We thank Dr Paul Sypherd for helpful discussion.

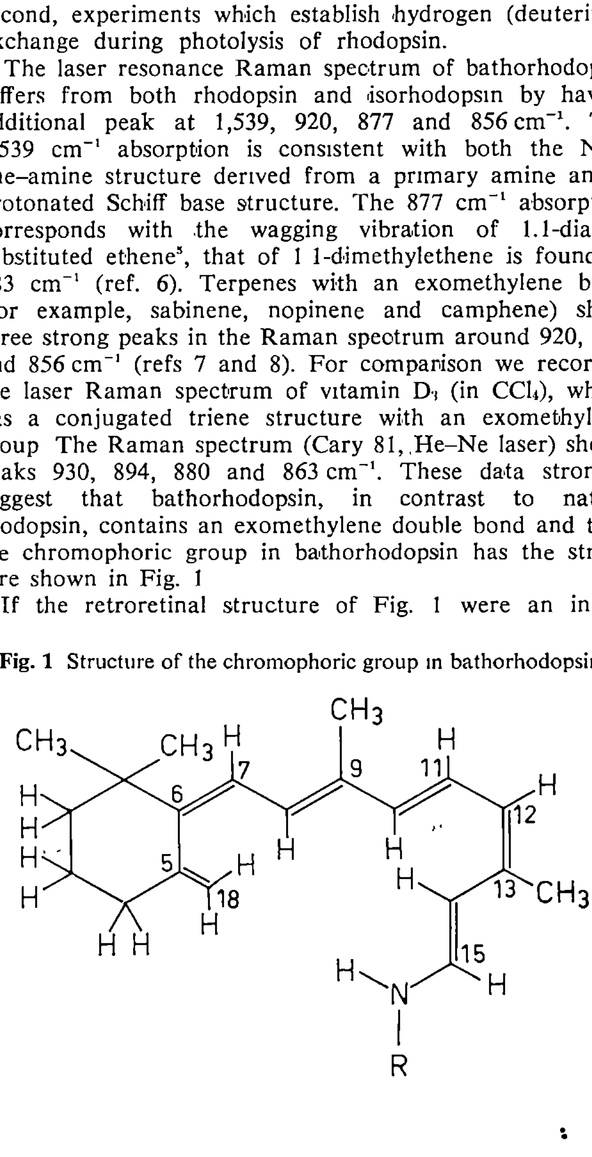
Structure of the chromophoric group in bathorhodopsin

IN the photolysis of the visual pigment rhodopsin the intermediate first observed is bathorhodopsin[1,2] (formerly called prelumirhodopsin). It is generally held that isomerisation of 11-*cis* to all-*trans* retinal occurs during this initial step. On theoretical grounds, however, an hexaene–amine structure (Fig. 1) has been proposed as an alternative for the chromophore of bathorodopsin (ref 3 and unpublished results of K. Van der Meer, J. J. C. Mulder and J.L.). This chromophore has an exomethylene double bond between the atoms C5 and C18 and the nitrogen of its ene–amine moiety derives from the ε-amino group of a lysine residue of opsin. It is a retrotautomer of the chromophoric group in native rhodopsin which is a protonated Schiff base of 11-*cis* retinal We now present two lines of evidence which support the structure depicted in Fig. 1: first, the interpretation of a recently published laser resonance Raman spectrum of bathorhodopsin[4], and second, experiments which establish hydrogen (deuterium) exchange during photolysis of rhodopsin.

The laser resonance Raman spectrum of bathorhodopsin differs from both rhodopsin and isorhodopsin by having additional peak at 1,539, 920, 877 and 856 cm^{-1}. The 1,539 cm^{-1} absorption is consistent with both the N–H ene–amine structure derived from a primary amine and a protonated Schiff base structure. The 877 cm^{-1} absorption corresponds with the wagging vibration of 1.1-dialkyl substituted ethene[5], that of 1 1-dimethylethene is found at 883 cm^{-1} (ref. 6). Terpenes with an exomethylene bond (for example, sabinene, nopinene and camphene) show three strong peaks in the Raman spectrum around 920, 877 and 856 cm^{-1} (refs 7 and 8). For comparison we recorded the laser Raman spectrum of vitamin D_3 (in CCl_4), which has a conjugated triene structure with an exomethylene group The Raman spectrum (Cary 81, He–Ne laser) shows peaks 930, 894, 880 and 863 cm^{-1}. These data strongly suggest that bathorhodopsin, in contrast to native rhodopsin, contains an exomethylene double bond and that the chromophoric group in bathorhodopsin has the structure shown in Fig. 1

If the retroretinal structure of Fig. 1 were an inter-

Fig. 1 Structure of the chromophoric group in bathorhodopsin.



mediate in the rhodopsin photolysis in the process of reconstituting the 18-CH_3 group in all-*trans* retinal, the ultimate product of rhodopsin photolysis *in vitro,* a hydrogen atom (proton) should be reattached to the 18-CH_2 group in one of the thermal reactions following the formation of bathorhodopsin. Then, hydrogen exchange between chromophore and apoprotein during photolysis might be detected by means of deuteration (or tritiation) of the latter and analysis of the chromophore. In spite of the negative outcome of an earlier attempt to detect tritium exchange during rhodopsin photolysis[3], various considerations led us to reinvestigate this approach in a slightly modified manner.

In a first attempt, rhodopsin, isolated as rod outer segments from 60 bovine eyes by a sucrose gradient technique[9], was washed repeatedly with D_2O and lyophilised. After incubation in D_2O in various conditions, the sample was irradiated with orange light for 30 min. The suspension was brought to 60% (v/v) ethanol and extracted with hexane. The retinal was isolated (thin-layer and high pressure liquid chromatography) in pure form. The samples were placed in an AEI MS-902 mass spectrometer through the direct, heatable introduction system. Spectra were taken, slowly heating the sample from 40 to 120 °C. From the retinal isolated, eight complete mass spectra, each at probe temperatures of 40, 60, 90, 100 and 120 °C, were obtained. At 100 and 120 °C, 20 spectra in the parent peak region were taken. The mass spectra thus obtained closely resemble those published for all-*trans* retinal[10]. In three independent experiments in which the incubation conditions with D_2O are varied (0 °C, 14 h; 0 °C, 18 h; 20 °C, 18 h), however, no deuterium incorporation was found in the chromophore.

This result might be explained by the possibility that D_2O has no access to the region of direct protein–chromophore interactions in rhodopsin Chances for more complete deuteration of the apoprotein could be better in opsin, where the chromophore is absent. Therefore, opsin, isolated as rod outer segments in room light[9], was washed repeatedly with D_2O and lyophilised The preparation was resuspended in D_2O and after incubation for various times a fivefold molar excess of 11-*cis* retinal was added. After 1.5 h rhodopsin regeneration, the preparation was centrifuged and the pellet was extracted three times with hexane to remove the excess of retinal. The residue containing regenerated rhodopsin was resuspended in D_2O. Samples of illuminated and unilluminated rhodopsin were extracted, purified and submitted to mass spectrometry as described above. The results are presented in Table 1.

In five independent experiments, deuterium incorporation to the extent of 6 ± 1% of one D atom was found in the all-*trans* retinal extracted from illuminated samples, as determined from the peaks of $m/e = 284$, 285 and 286, calculated according to Beynon and Williams[11]. In the control experiments, the chromophore extracted from unilluminated samples (largely 11-*cis* retinal as shown by thin-layer chromatography) did not show any deuterium incorporation. This demonstrates that deuterium is incorporated in the chromophore as a result of illumination.

The accepted mechanism for the photolysis of rhodopsin is based on a photochemical *cis-trans* isomerisation of the chromophoric group[12]. Since retinal does not show H-D exchange, in either thermal or photochemical conditions, our observation of a light-induced H-D exchange in the chromophore of rhodopsin is difficult to explain by such a model. We have proposed another mechanism, in which a hydrogen shift is introduced as the photochemical step, resulting in a hexaene-amine moiety as structure for early photointermediates of rhodopsin photolysis (unpublished results of K. Van der Meer, J. J. C Mulder and J. L) This model leaves two possibilities for the exchange of hydrogen between chromophore and apoprotein. The hydrogen donated to the apoprotein is either not that which is returned in reconstituting the chromophore or it is later reattached to the chromophore.

Table 1 Percentage of deuterium incorporation in retinal extracted from rhodopsin obtained by regeneration from D_2O-incubated opsin and 11-*cis* retinal

Opsin incubation with D_2O (°C, h)	11-*cis* Retinal from rhodopsin before illumination	all-*trans* Retinal from rhodopsin after illumination
20, 1	—	6
20, 5	—	5
20, 14	0	5
20, 18	0	7
30, 14	—	7

In the first case, 100% monodeuteration could be expected if the hydrogen-donating site on the apoprotein is completely deuterated. But our observation that the percentage of deuterium exchange is low and independent of the time during which opsin is incubated with D_2O (Table 1), suggests that such a hydrogen-donating site may not exist In the second case, one would not necessarily observe H–D exchange; exchange might occur during the time the shuttling hydrogen spends on the protein. We suggest that the very short lifetimes of the photointermediates, bearing a hexaene–amine as chromophore, are responsible for the relatively low deuterium incorporation in retinal during photolysis.

In conclusion, the laser resonance Raman spectrum of bathorhodopsin and the occurrence of hydrogen exchange between chromophore and apoprotein during photolysis support a hydrogen shift as the primary event in the photolysis of rhodopsin.

Crystal structure of cholesterol monohydrate

Cholesterol, almost water insoluble, normally occurs in the body bound to lipoprotein, or incorporated in lipid aggregations such as bile micelles, or within certain biomembranes. When cholesterol levels are abnormally high, single crystals of the monohydrate tend to deposit; in bile, clumps of these crystals form gallstones[1]. Crystals of cholesterol monohydrate also

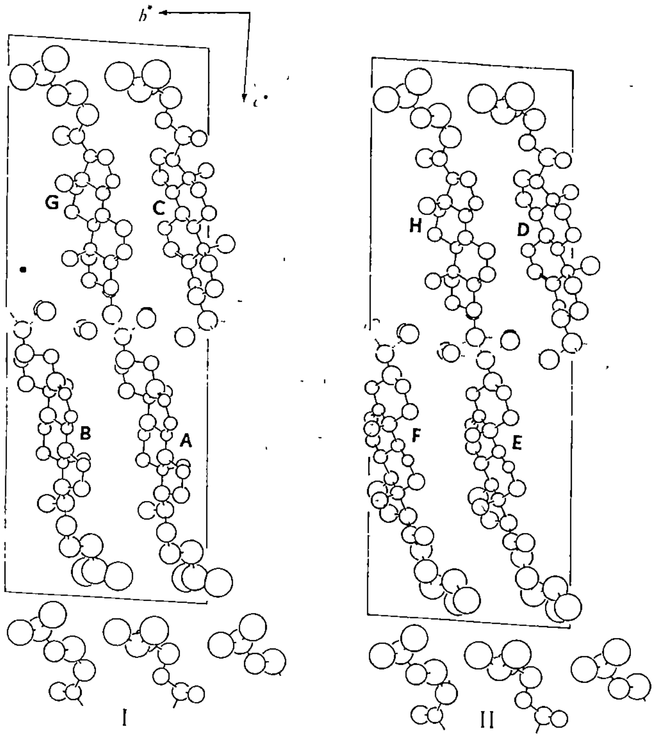

Fig. 1 Crystal structure of cholesterol monohydrate projected down *a* (into page), with II superposing on I to give the complete structure. Molecules in the pairs (A, B), (E, F) are related by translations *b*/2, and in the pairs (C, D), (G, H) by *a*/2. Circles represent isotropic thermal motion, being drawn at the level of 50% probability of enclosing an atom.

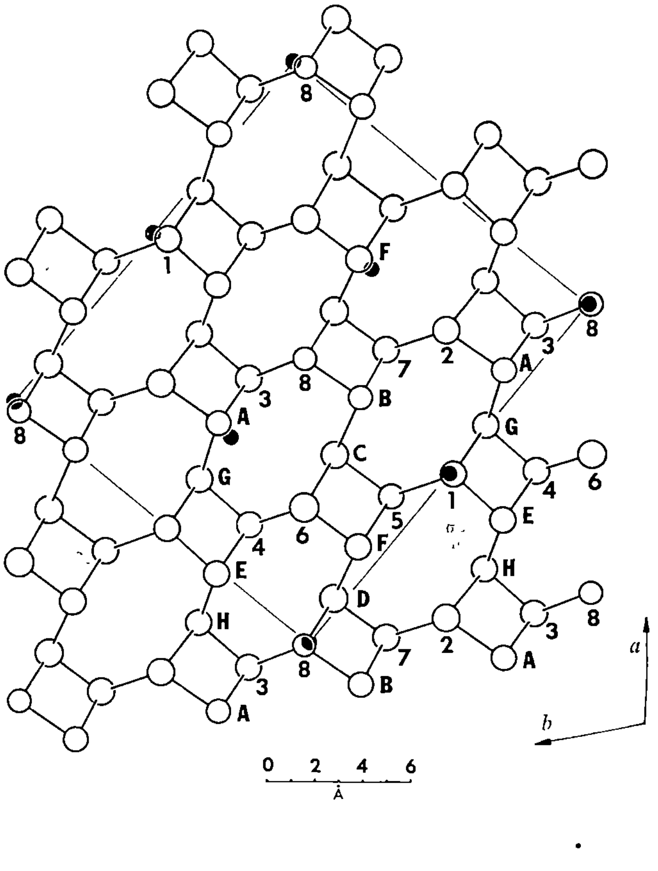
occur in atherosclerotic lesions[2]. Earlier reports of crystal data for cholesterol monohydrate are not all consistent, although they indicate a structure of unusual complexity (refs 1, 3–5 and S. H. Kim and W. Warrant, personal communication). The crystal structure (Fig. 1) has now been determined by a molecular replacement method which was developed primarily for protein crystallography[6].

A crystal of dimensions 0.4×0.15×0.10 mm along the *a*, *b*, *c* directions, grown from acetone–water solution and sealed in a lacquer coating, was examined by CuKα X-ray precession photography and by computer-controlled diffractometer. From comparison of the $h\bar{h}l$ net with Fig. 2 in ref. 1, the crystalline form appears to be the same as described previously[1,3]. The diffraction symmetry may well be mistaken for monoclinic, with $(4\bar{4}1)^*$ as the approximate twofold axis. There are, however, significant differences in intensities of rows such as 02*l* and 20*l* which reveal the true triclinic symmetry. The space group is thus P1, with reduced cell parameters $a=12.39$, $b=12.41$, $c=34.36$ Å, $\alpha=91.9$, $\beta=98.1$, $\gamma=100.8°$. The density (1.045 g cm^{-3}) measured for a crystal from the same mother liquor, and quickly transferred and suspended in a sucrose–water solution, agrees with the calculated density (1.048 g cm^{-3}) assuming the unit cell to contain $8(C_{27}H_{46}O).8H_2O$ (molecular weight, 3,240). Among the measured 10,157 independent X-ray reflections with $\sin\theta/\lambda < 0.5$ Å^{-1} ($d_{\min}=1$ Å) only 2,480 with intensity $I > 2\sigma(I)$ were obtained, and used in the structure determination. The high proportion of weak reflections was due to the large amplitudes of atomic thermal vibrations (overall isotropic $B=7.6$ Å^2) and to a remarkable systematic absence of reflections *hkl* with *h* and *k* both odd. These absences were previously assumed to indicate macroscopic twinning on (001), consistent with the almost equidimensional *a* and *b* cell edges[1]. It is, however, impossible to resolve the reciprocal lattice reported here into two identical sublattices with a common *c**, because the angles α* and β* are significantly different (86.5° and 81.4° respectively). It seemed that the twinning must be within the cell unit. A structural model, later shown to be correct, was based on two nearly identical but differently oriented subcells with translations (*a*, *b*/2) and (*b*/2, *a*). The first subcell structure (for example molecules A, E and B, F, Fig. 1) would contribute no diffracted intensity to reflections *hkl* with *k* odd, and the second (for example, molecules C, G and D, H) would contribute nothing to those with *h* odd, thus explaining the systematic absences. This model was consistent with the maps of the Patterson rotational and translational searches[7] and was helpful in their interpretation. Eight 20-atom cholesterol fragments were located by comparing the observed Patterson function with that of the same artificial 20-atom structure which was recently used in the crystal structure determination of cholesteryl myristate[8]. All 232 non-hydrogen atoms were found in subsequent electron density maps. Positional and isotropic thermal parameters were refined by a block diagonal least squares procedure to a present *R* index of 0.12. Estimated standard deviations in bond lengths are about 0.06 Å. Hydrogen atoms were included at calculated positions by assuming C–H bond distances of 1.0 Å and tetrahedral or trigonal bond angles. Hydrogen-bonded hydrogen atoms were not found and thus not included in structure factor calculations. The C(17) chain atoms have large thermal mean square amplitudes of vibration, ranging from 0.25 to 0.40 Å^2, but there is no evidence of disorder with respect to different conformers.

The structure shows a stacking of bilayers of thickness $d_{001}=33.9$ Å. The ring systems of all cholesterols are nearly parallel to (111) with the long axes nearly along $[\bar{1}24]$, which makes an angle of 17.4° with *c**. Molecules such as A and B which are related by subcell translations have the same conformation. Molecules such as A and G which are related by

Fig. 2 A hydrogen-bonded sheet, projected down *c** (into page). Open circles represent thermal parameters for oxygen atoms, as in Fig. 1. Hydroxyl groups are labelled alphabetically and water oxygen atoms numerically. Solid circles represent the hydroxyl ion configuration in the (001) plane of hydroxyapatite. Outlined is a supercell of the hexagonal hydroxyapatite structure.



approximate local twofold symmetry have similar conformations, and molecules such as A and E within the same subcell have different conformations. Thus in A, the C(17) chain is twisted towards the β side of the molecule, whereas in E the twist is towards the α side, so that the two chains are approximately parallel in the crystal. None of the molecules has a fully extended C(17) chain, such as was found for one of the two different rotamers in cholesteryl myristate. The partial folding of all C(17) chains in cholesterol monohydrate results in a condensed structure at the centre of the bilayer.

In projection down [$\bar{1}$24], the subcell for cholesterol packing gives a net with $a_s=12.19$, $b_s=6.10$ Å, and $\gamma_s=103.4°$ and an area of 36.2 Å^2 per molecule. In the bilayers of the crystal structure of cholesteryl myristate[8], the subcell for cholesterol packing also contains two parallel molecules, the cross-sectional area being 36.6 Å^2 per molecule. The packing, however, is different. In cholesterol monohydrate, the projecting C(18) and C(19) methyl groups from discrete pairs of molecules (for example A and F) are at van der Waal's distances, whereas in cholesteryl myristate, such distances occur between a given molecule and two neighbouring molecules, thereby forming infinite chains of methyl–methyl interactions.

The C(3) hydroxyl groups and water molecules are hydrogen bonded to form a pleated sheet at the bilayer interface (Fig. 2.) Each oxygen atom forms three hydrogen bonds, so that there are 24 distinct O· · ·O distances which range from 2.68 to 3.01 Å. The average distance (2.86 Å) is on the long side of the reported distribution for other organic hydrates (average 2.80 Å with an e.s.d. of 0.09 Å (ref. 11)). This, together with the rather high values for the mean square thermal amplitudes of vibration of the oxygen atoms ($0.11 < \overline{u^2} < 0.16$ Å^2), suggests that the hydrogen-bonding network is weak, and that the water molecules have an important space-filling role in stabilising the structure during crystal growth. Migration of water molecules along the tunnels parallel to a, in which they lie (Fig. 1), provides an explanation for the ease with which the crystals dehydrate on exposure to air.

Epitaxial relationships between crystal structures may be important in nucleating the deposit of crystals in biological systems[10]. Crystals of both hydroxyapatite and cholesterol monohydrate usually develop (001) faces. The hydroxyl ions of hydroxyapatite are in planes parallel to (001) with O–H bonds favourably oriented for hydrogen bonding at the (001) crystal surface[11]. A fit of the (001) planes shows close superposition of hydrogen bonding groups from the two crystal structures. The corresponding superlattice nets (Fig. 2) have $a=18.84$, $b=16.31$ Å, $\gamma=90°$ for hydroxyapatite and $a=19.13$, $b=15.84$ Å, and $\gamma=90.1°$ for cholesterol monohydrate. With the intervention of a transition layer of hydrogen-bonded water molecules, a microcrystal of either structure may serve as a nucleus for growth of the other. Since atherosclerotic plaque from recently deceased patients has been shown to contain crystalline hydroxyapatite[12], it is possible that cholesterol monohydrate is implicated in the calcification often associated with later stages in the development of such lesions.

Accessible area, packing volumes and interaction surfaces of globular proteins

I RE-EXAMINE here the recently published empirical equations of Chothia[1] for the accessible surface area of 12 monomeric proteins, and demonstrate that accessible surface area of monomeric proteins varies as the 2/3 power of the molecular weight. The total packing volumes of proteins are obtained from the sum of the individual residues, and the approximation of proteins as spheres is used to predict the loss of accessible surface on association of two proteins. The treatment is extended to calculate the proportion of the monomer surface buried in the formation of higher oligomers.

The total accessible area (in Å^2) of the polypeptide chain in the extended form, A_t, was found to be a linear function of molecular weight, M, as it should be since each additional residue contributes on average a fixed area. If A_s is defined as the accessible surface area of the folded protein chain, $A_b=A_t-A_s$ is the accessible surface area that is buried when the protein folds. Chothia proposed that

$$A_t=1.44\,M \tag{1}$$

$$A_b=0.859\,M+0.774\times10^{-5}\,M^2 \tag{2}$$

It follows that

$$A_s=0.581\,M-0.774\times10^{-5}\,M^2 \tag{3}$$

Equation 3 implies that the accessible surface is zero at $M=75{,}000$, which does not seem reasonable. Moreover, since the proteins are globular it is reasonable to assume that A_s should should vary as $M^{2/3}$.

Using Chothia's data for 12 monomeric proteins, I found by least squares analysis that

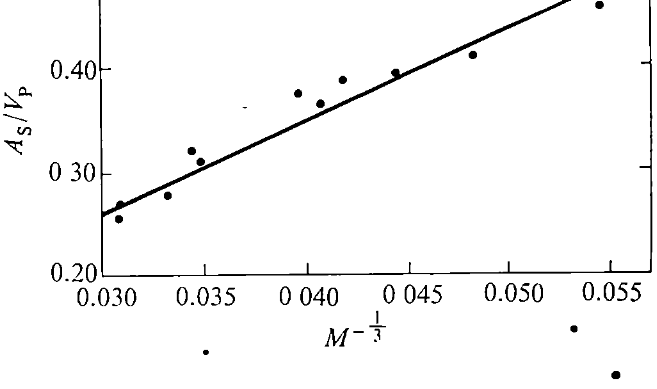
$$A_t=(1.449\pm0.006)\,M\,(\text{standard error}=417\text{ Å}^2) \tag{4}$$

$$A_s=(11.116\pm0.161)\,M^{2/3}\,(\text{standard error}=401\text{ Å}^2) \tag{5}$$

The standard error of the fit to the data in equation 5 is not much below the standard error of 428 Å^2 obtained from the data using equation (3); there are several other reasons, however, that demonstrate that equation 5 has the correct form. First, least squares analysis of log A_s as a function of log M yielded 0.685 ± 0.027 as the slope, verifying the 2/3 exponent for M in equation 5. A second argument for equation 5 comes from the area buried on folding the protein. Subtraction of equation 5 from equation 4 gives

$$A_b=1.449\,M-11.116\,M^{2/3} \tag{6}$$

Fig. 1 Molecular weight dependence of the surface–volume ratio. The solid line corresponds to equation 8. A_s is the accessible surface area and V_p is the total packing volume.



This equation yields zero buried area at $M=451$, a reasonable physical limit. Outside the range of M between 10^4 and 3.5×10^4 equations (2) and (6) differ significantly.

I have estimated the total packing volume of these proteins by simply summing the packing volumes of all protein residues in the primary sequences using the volumes of buried residues given by Chothia[1]. The value for the arginyl residue was estimated from the correlation between residue partial specific volumes[2] and packing volumes for the remaining 19 residues. The values calculated for lysozyme and ribonuclease agree closely with those of Richards[3]. Defining V_p as the total packing volume, I found the following empirical relationship for the 12 proteins

$$V_p=(1.273\pm0.006)\,M\,(\text{standard error}=401\ \text{Å}^3) \qquad (7)$$

From equation (5) and equation (7), the surface–volume ratio should vary as $8.733\,M^{-1/3}$. The least squares equation found is,

$$A_s/V_p=(8.768\pm0.102)\,M^{-1/3}\,(\text{standard error}=0.015\ \text{Å}^{-1}) \qquad (8)$$

Figure 1 shows this surface/volume relation to be reasonable. The exponent of M in equation 8 was verified by analysis of log A_s/V_p against log M. The exponent found was -0.331 ± 0.021.

Variation of accessible surface area as $M^{2/3}$ for these monomeric globular proteins implies that in protein–protein complexes, protein subunits may be treated as spheres. In packing volume, monomeric proteins behave as if they possessed the radius,

$$R_p=\left(\frac{3V_p}{4\pi}\right)^{1/3}=\left(\frac{3\times1.273}{4\pi}\right)^{1/3}M^{1/3}=0.6723\,M^{1/3} \qquad (9)$$

In accessible surface area, the same proteins seem to have radius R_s

$$R_s=\left(\frac{A_s}{4\pi}\right)^{1/2}=\left(\frac{11.116}{4\pi}\right)^{1/2}M^{1/3}=0.9405\,M^{1/3} \qquad (10)$$

Thus, for monomeric proteins R_s is 1.4 R_p. The physical interpretation of this is that the larger value of R_s comes from the roughness of the protein surface.

Chothia and Janin[4] have demonstrated that the packing volume in the interface between associated proteins is the same as in the proteins themselves. Therefore, on tight protein association, total packing volumes should be additive. On the other hand, some accessible surface becomes buried. Figure 2 shows how this can happen: the total packing volume is conserved in the complex, but the spheres for the surface lose area upon contact. To calculate the accessible surface area buried on association, one need only determine the surface area of overlap. Table 1 compares the results of calculations made in this way with those of Chothia and Janin[4]. While not exact, the agreement is remarkably good considering the simplicity of the model. For the dimerisation of identical monomers, the problem can be generally written as, $S_b=2\pi R_s(R_s-R_p)=0.143A_s$. S_b is the surface buried per monomer and A_s is the accessible surface of a monomer as in equation 5. Thus, in general, close association of monomers to form a stable dimer involves a loss of 14.3% of accessible surface area per monomer.

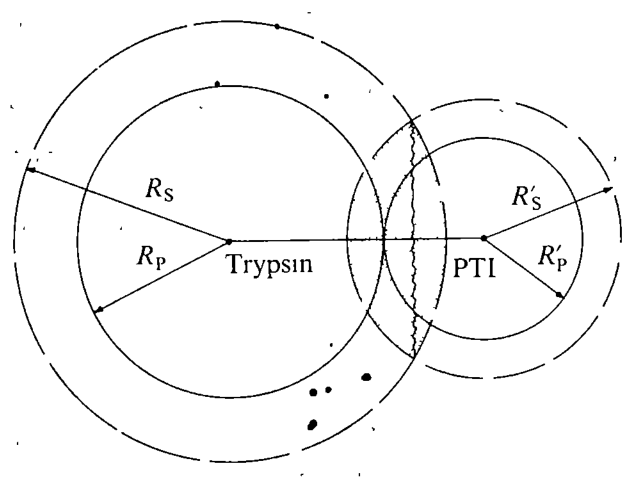


Fig. 2 Schematic diagram of association of trypsin and pancreatic trypsin inhibitor (PTI). The packing radii are represented by R_p and R_p' and the solid circles. The accessible surface radii are denoted by R_s and R_s' and the dashed circles. Accessible surface area which is buried on association is denoted by the overlap of the dashed circles (stippled area). The wavy line denotes the partition of buried accessible surface to the interacting proteins.

In a square planar tetramer of identical monomers, each monomer contacts two subunits. Thus, each monomer is predicted to lose 28.6% of its accessible surface in the tetramer. The packing of 4 spherical volume elements into a tetrahedral tetramer by this model gives a double burial of some accessible surface area. Neglecting this area of overlap, the geometrical prediction from the model is that 43% of accessible area of the monomeric subunit becomes buried on association with this type of tetramer.

The predicted value of accessible surface area for the concanavalin A monomer from equation 5 is ~ 6% lower than observed[1]. Thus, at present, it is not certain that equation 5 can be used to predict accurately accessible surface of monomers with complex arrangements of subunits in the oligomer.

Table 1 Predicted and observed changes in accessible surface area

Complex	Molecular weight	Total accessible surface area (Å²) Predicted	Total accessible surface area (Å²) Observed	Area buried in complex Value Predicted	Area buried in complex Value Observed	Area buried in complex % Predicted	Area buried in complex % Observed
Insulin dimer							
Monomer M_1	5,787	3,583	3,400	512	530	14	16
Monomer M_2	5,787	3,583	3,310	512	600	14	18
Total change				1,024	1,130		
Trypsin-PTI							
Trypsin	23,302	9,069	8,920	737	640	8	7
PTI	6,158	3,735	3,700	889	815(750)*	24	22(20)*
Total change				1,626	1,455		
Horse haemoglobin							
α chain	15,114	6,795	6,940	991	930	15	13
β chain	15,979	7,052	7,130	983	790	14	11
Total change				1,974	1,720		

*750 Å² was determined from the complex; 815 Å² was found when free PTI coordinates were used.

Nonetheless, the previous considerations indicate that a vast amount of accessible surface becomes buried during the acquisition of quaternary structure. The biological significance of this loss of surface area in relation to oligomeric protein size and structure remains to be established.

I wish to thank Christoph de Haen for discussions, and the National Institutes of Health for support.

Increasing effects of repetitive cocaine administration in the rat

Reports of chronic cocaine (and related psychomotor stimulant) administration suggest that tolerance develops to many drug effects[1–3]. A few studies of high dose cocaine administration have suggested that, on the contrary, repetitive administration may be associated with increasing effects on cocaine-induced convulsions in the rat[4,5] and monkey[6] and increasing bizarre visual and inhibitory behaviour, as well as dyskinesias, in the monkey[6]. We now report for the first time that repetitive cocaine administration can be associated with progressively increasing effects on horizontal and vertical hyperactivity as well as stereotypy in the rat.

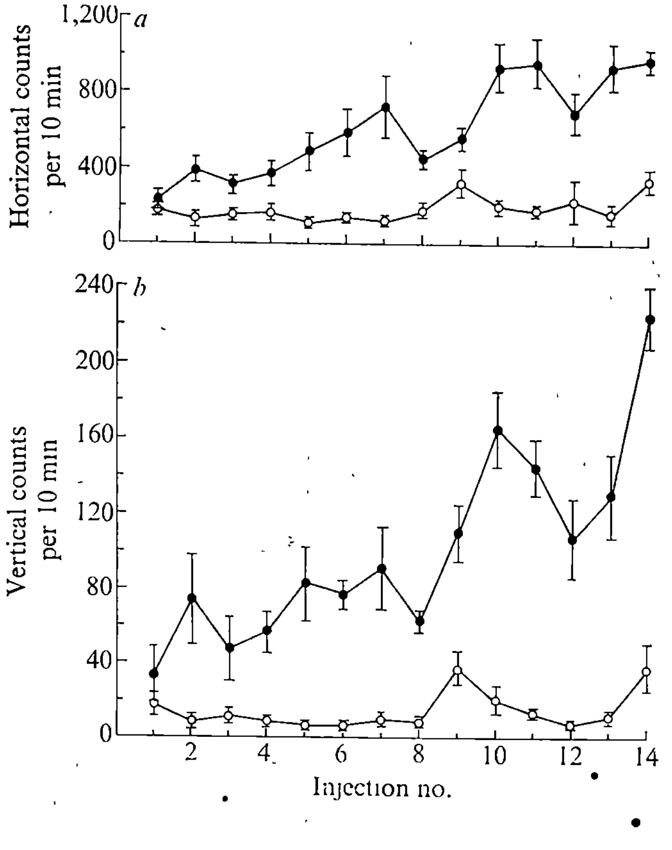
Sixteen male Sprague–Dawley rats weighing 150–185 g were maintained in groups of 3 or 4 animals per cage on a 12-h light–dark cycle. Eight rats received intraperitoneal injections of cocaine 10 mg kg^{-1} once daily, with two drug-free days each week. Eight saline-control animals received an equal volume of injection on a similar basis. Animals were removed from their home cages and tested in a 24×24×15 cm Plexiglas chamber. After a 20-min period of adaptation, animals were injected with cocaine or saline, replaced, and monitored in 10-min intervals for 90 min. Each animal was tested at the same time of day, either 0900, 1100, 1300 or 1500, during the light phase of the cycle. Cages were placed on top of 40 infrared photoelectric cells (Motron motility meter) for measurement of activity counts. Slight horizontal movements of the rats, and not just gross locomotor activity, registered as activity counts because of the density of the photocells. Five photoelectric cells positioned 13 cm above the floor of the cage measured vertical activity. Animals were also rated for degree of stereotypy ranging from 0 for absent to +4 for intense, continuous stereotypic patterns during a given 10-min interval.

The animals showed increased horizontal and vertical hyperactivity and stereotypy in response to the repeated cocaine injections. Figure 1 illustrates the increase in horizontal and vertical hyperactivity over the course of 14 injections (both $P<0.001$, 2-way analysis of variance for repeated measures). Figure 2 documents the course of the progressive development of vertical and horizontal hyperactivity, and shows an increase in both peak effects and duration. Following the first few injections, the animals' activity had returned towards the baseline by 60–90 min; while after 15 injections, the activity was still near peak levels at this time. Stereotypy ratings increased from 0.4 ± 0.1 following the first injection to 3.2 ± 0.1 following injection 14. Initially, animals displayed mild repetitive sequences moving from corner to corner, rearing on haunches, and quick circular movements of the head. These patterns were initiated earlier and became progressively more intense, redundant, and prolonged following later injections. For example, rats would engage in frantic, persistent head circling or bobbing while lying prone, or repetitively raise and lower themselves on their haunches with no change of pattern for as long as 15 min.

Conditioning phenomena, as suggested by Tilson and Reich[7], do not appear to account adequately for these progressive increases in hyperactivity and stereotypy. For injection 25, instead of receiving their usual cocaine injection, experimental animals received saline. As illustrated in Fig. 2, these animals reacted with minimal hyperactivity and stereotypy, not significantly different from saline control animals. Similar results and arguments have been presented by Segal and Mandell[8] for the progressive effects of continued amphetamine administration on behaviour, again supporting the idea that conditioning effects are not an adequate explanation of the phenomenon. Although increased blood or brain cocaine levels with chronic administration must be carefully ruled out, preliminary evidence in the rat[9] and monkey (R. Hawks and R. M. P., unpublished) suggests that the peak levels and half life of cocaine in blood and CSF do not increase with chronic administration. After 24 injections, the weights of cocaine treated animals (240 ± 11 g) were similar to that in saline controls (245 ± 9 g), indicating that differential weight loss or debilitation did not account for the progressive effects.

Our data thus suggest that repetitive administration of cocaine is capable of producing increasing hyperactivity and stereotypy in some conditions of administration. Whether tolerance can be manifested may depend not only

Fig. 1 Increasing effect of repeated cocaine injections on (*a*) horizontal activity and (*b*) vertical activity. ●, cocaine (10 mg kg^{-1}; $n=8$); ○, saline ($n=8$).



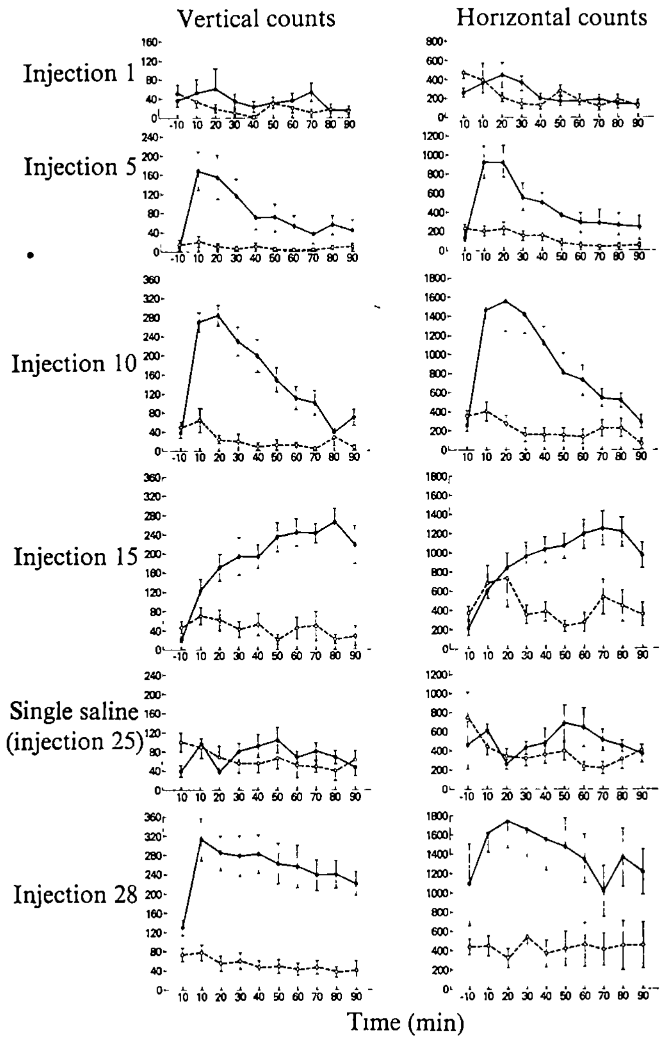


Fig. 2 Effects of repetitive injections on time course of cocaine-induced hyperactivity.

on the specific parameters studied[1-3], but also on the intermittent rather than continuous drug administration. Previous studies have documented that repetitive, intermittent, high dose cocaine administration could be associated with progressive increases in a variety of effects in the rat, dog, and monkey, including seizures, catalepsy, motor inhibition, visual tracking behaviour, and dyskinesias[4,6,10,11] That the lower doses of cocaine administration used here are also capable of producing progressive effects suggests that the phenomenon is not merely a toxic manifestation of high dose administration.

We have suggested that some progressive effects of repetitive administration of cocaine[6,12] as well as the local anaesthetic, lidocaine[13], seem very similar to those of electrical kindling[14-17] in which repetitive electrical stimulation of the limbic system is associated with increasing afterdischarge activity and eventually in major motor convulsions at previously subthreshold stimulation. Since cocaine and lidocaine produce marked effects on limbic spindles, after-discharges, and seizure activity[18,19], it is possible that a kindling-like mechanism, increasing duration and spread of electrical activity, could account for the progressive effects of lower doses of cocaine where convulsions are not involved as an endpoint. Consistent with a kindling mechanism, Ellinwood *et al.*[20] and Stripling and Ellinwood[21] have reported the increased spread of electrical discharges in cats and rats with chronic cocaine administration.

Many different biochemical mechanisms could also be involved in the apparent sensitisation to cocaine effects including pre-[22,23] or post-synaptic[24,25] alterations, or progressive changes in the activation[26,27] or binding[28] of different kinds of receptors. Rebec and Groves[29] reported that repetitive amphetamine pretreatment increased the effect of iontophoretically administered amphetamine and apomorphine on striatal and reticular formation neurones, supporting the concept of an increased receptor sensitivity with chronic stimulant administration[25]. Gunne and Jonsson[30] reported that cocaine injections (100 mg kg^{-1}) once daily for 14 d produced increasing effects on urinary, but not brain, adrenaline and noradrenaline. Study of the biochemical substrates for the progressive behavioural effects of cocaine[31] and their possible relationship to a kindling process[32], may help elucidate the mechanisms involved in the stimulant induced psychoses of man.

Fascination for discovery

Dorothy C. Hodgkin

The Development of X-Ray Analysis. *By the late Sir Lawrence Bragg. Edited by D. C. Phillips and H. Lipson. Pp. viii + 270. (Bell: London, 1975.) £6.50.*

THIS book is a joy to read. Over and over again one can almost hear W. L. Bragg talking, as he used to talk when he was with us, always himself fascinated by the problem of solving the next crystal structure, telling us stories meanwhile about the past, mildly debunking, still illuminating.

His point of departure in this book is the discovery of X rays by Röntgen in 1895 and Röntgen's own extensive experiments on their nature. These lead to a general discussion of the evidence for the nature of light and of fundamental particles, and so to the discovery of X-ray diffraction itself, and to the experiments which followed on the structure of crystals and of atoms. In small asides he recaptures moments in the past. "I remember well a fellow student at Jeans' lectures on quantum mechanics, who used to take me aside after the lecture and give me long dissertations on just where Jeans was wrong. This was Bohr—I little knew at the time how great a man was talking to me."

It was one of the important characteristics of W. L. Bragg's own work that he believed in exact and beautiful experiments. So details are given throughout the book of the actual apparatus used and also of the conditions in the different laboratories in which research was organised. He wrote of the Cavendish laboratory of his time "When I achieved the first X-ray reflections I worked the Rumkorff coil too hard in my excitement and burnt out the platinum contact. Lincoln, the mechanic, was very annoyed, as a contact cost ten shillings, and refused to provide me with another one for a month . . . I could never have exploited my ideas about X-ray diffraction under such conditions." He moved, in fact, to Leeds, to his father's laboratory, where the facilities were on a very different scale, the consequences of W. H. Bragg's own past experience of setting up a physics laboratory of his own in Adelaide.

To solve the first, quite unknown, crystal structures, W. L. Bragg developed direct and simple arguments, leading to unambiguous answers, and based on a thorough understanding, which he illustrates fully, of optical principles and Fourier analysis. The details of structure determination changed a little as each new family of crystal structures was explored—complex ionic compounds, organic compounds, metallic structures, macromolecules. He took great pleasure in the actual structures found, and this is described in a series of chapters, which end with one on imperfect crystallisations on problems for the future. He also took pleasure in using some of the same simple arguments with which he had solved his first structures to guide the analysis of the most complicated ones, particularly of proteins. His one major omission in the book—any treatment of the statistical approach to phase determination now found in use to be very powerful—probably stems from his liking for unambiguous choices. To examine a series of very probable answers did not appeal to him, even if modern computing and his own contributions to structures solved made choice between them easy.

Not surprisingly in a book published posthumously, a few small errors appear, some of which seem sufficiently interesting historically to mention. The first is perhaps obvious—the photograph interpreted by von Laue on p17 is, as mentioned in the text, zinc blende, not copper sulphate (not interpreted till long afterwards). On p107, the map shown is not of a part of vitamin B_{12} but of the first synthetic corrin derivative—nice indeed that the electron density here was computed to demonstrate that the correct chemical synthesis had been achieved. On p112, the structure shown in Fig. 4a has a negative peak at the hexagon centre, not a positive peak as described in the text. It illustrates a deduction of Dorothy Wrinch's that the centre of the insulin unit cell should be relatively empty to account, in terms of her theory, for the observed Patterson peak heights. And finally, on p181, Bernal's first indications of the sterol structure were obtained in 1932, not 1943.

This is a book for many different kinds of reader—beginners in X-ray analysis who want to get a feel of the subject, old hands who wish to remember the past, students in other fields who would like to know something of a fascinating region of knowledge and of those who discovered it. We are deeply indebted to Professor Phillips and Professor Lipson for preparing it for publication. □

Vital statistics

Collected Papers of R. A. Fisher. Five Volumes. Edited by J. H. Bennett. (University of Adelaide: Adelaide, 1971–74.) A$87.00.

THE University of Adelaide has completed its five-volume edition of the scientific papers of the late Sir Ronald Fisher. These preserve the original typography of the nearly 300 items, and make available, in very agreeable form, all Fisher's important publications in scientific journals and some short articles of more general interest. Unlike other great scientists of this century, Fisher has not been widely known to the public, yet few men have so much changed the face of science. In statistical theory, he has profoundly influenced even those who differed from him philosophically. Almost every field of quantitative experimental and observational science has been affected by considerations of experimental design, of randomisation, and of the practice of statistical tests and inference, most of which can be traced to the impact of Fisher's papers and books between 1920 and 1935. To those who knew Fisher, there is special delight in again savouring the intellectual excitement that the early papers produced and the highly individual style of the author. The argument is often difficult, sometimes obscure, but always strikingly presented. To look again at "Two new properties of mathematical likelihood" is to gain insight into the real nature of statistical inference, so often concealed by the wrappings of rigour in later developments. A series of papers on the rhesus blood factor shows how statistical thought contributed to the unravelling of a genetic complexity—in retrospect simply, but highly controversial at the time. "The logic of inductive inference" remains not only a classic in the development of statistical inference but a superb example of scientific disputation enlivened by human passion. Any library with pretensions to coverage of statistics and statistical genetics needs these volumes, not merely for their historic interest but also for their continuing powers to stimulate new thought, and for the contrast with the pedestrian style and content of so much modern statistical writing.

D. J. Finney

Control theory

Control Theory in Biology and Experimental Psychology. By F. M. Toates. Pp. 264. (Hutchinson Educational: London, 1975.) £6.50.

ALTHOUGH many biologists, physiologists and psychologists realise that the concepts of control theory provide powerful unifying principles which relate not only the functional behaviour of diverse systems in their own fields, but also the physical systems of engineers and others, there is still great reserve concerning the benefits to be gained from a deep study of the theory. Although a certain amount of reluctance is due to unfamiliarity with the theoretical and numerical methods on which control theory is based, there are even more profound doubts concerning the ultimate usefulness of the subject. Before a biologist embarks on a long and often difficult study, in which he must become familiar with much of the usage of system and control engineers, he must be convinced that the outcome will offer at least one of several possible advantages. He may wish to formally pose problems which are ill-defined in non-numerical terms. Any theoretical or computer studies of a problem must produce results which at least should give reliable guides to the cause–effect relationship in his systems. He should feel confident to extend the use of any mathematical models developed to regimes beyond the scope of his experimental techniques. Above all, control theory should enable him to sharpen his choice of experiments and to plan a unique and unambiguous route of experimental deduction, for it is in the laboratory that the biologist makes his significant contributions.

There is a wealth of literature on control theory written for the specialist, but much of it is little considered outside the realms of the University. Faced with this, the biological scientist first has a considerable threshold of theoretical technique to overcome and then he must be able to discern which of the abundance of control theoretical techniques are useful to him. There is a distinct shortage of books which are written specifically for the biological sciences and which give a sufficient introduction to the mathematical rigour which will be needed. I have seen texts in which an introduction to control concepts has been attempted deliberately avoiding mathematics but, as Dr Toates knows, this is a sterile approach.

The present book approaches the problem squarely, attempting to show the importance of differential equations, and theoretical and numerical techniques for solving them, in studying the transient behaviour of any system. These methods are firmly set in a background of biological and psychological processes which, if somewhat basic, are useful enough to demonstrate the power of the techniques in analysis and deduction. The author has clearly concentrated on systems with which he is most familiar and has not tried to cover an extreme range of examples. The result is a neat text which the control engineer would find fascinating reading and which should lead the biologist gently into a more exacting study of this subject. Only when this step has been made will the considerable potential of control theory for the life sciences be realised.

Space odyssey

Pioneer Odyssey: Encounter with a Giant. By Richard O. Fimmel, William Swindell and Eric Burgess. Pp. 170 (NASA: Washington, 1975.) $5.50.

THIS is another in the series of commendable little books resulting from the recent (and continuing) exploration of the Solar System by NASA spacecraft. Although the book is in parts self-congratulatory, and reads in places like a publicity handout (which, in a sense, it is), the amount of worthwhile information and the spread of Jupiter pictures from Pioneer provide excellent value for the very modest cost. *Pioneer Odyssey* is highly suitable for use in introductory astronomy courses, but would serve equally well as an introduction to modern planetary science for someone specialising in another discipline but with a peripheral interest in the subject.

A lengthy introductory chapter describes Jupiter, "Giant of the Solar System"—the history of observations of the planet, how its structure probably differs from the terrestrial planets—and gives a thumbnail sketch of ideas concerning the formation of the Solar System. Although the central emphasis of the book is on the technology and techniques of this deep space mission, the section on scientific results from the Jupiter observations (and from study of the interplanetary medium) provides an excellently clear non-technical summary of the Pioneer 10 discoveries. This, and the whole book, is flawed only by the knowledge that Pioneer 11 has since made further investigations which fill out the overall picture rather more fully. I hope that the NASA/Ames team will be persuaded to produce a second edition with a fuller account of the new understanding of Jupiter in the light of Pioneer 11 data.

John Gribbin

Laser light

Plasmas and Laser Light. By T. P. Hughes. Pp. xxi+518. (Adam Hilger: London, October 1975.) £35.

LASER-related topics now hit the scientific headlines so frequently that it can become quite difficult to distinguish between actual achievement and future plans or aspirations. Confusion of this sort is perhaps inevitable in a field which is interdisciplinary, and which is still growing very rapidly. For example, in the US the relevant ERDA operating budget (supporting research and development administered by the Energy Research and Development Administration), currently totals some $90 million per annum. Research into laser isotope-separation techniques now constitutes a significant fraction of this budget, but laser fusion still continues to attract the lion's share of the funding. Within the UK a laser facility for fundamental scientific investigations has recently been established at the SRC's Rutherford Laboratory. In view of all the above developments, the recent publication of Dr Hughes' book is particularly opportune.

The historical background, some potential advantages, possible difficulties and competition for the laser-compression approach to controlled thermonuclear fusion have been outlined by me on previous occasions (*Nature*, **239**, 129 (1972); **251**, 99 and **252**, 631 (1974)). These topics constitute the dominant theme of the book, although magnetic containment and plasma diagnostics are also discussed briefly. *Plasmas and Laser Light* is a broad canvas and Dr Hughes has appropriately included an extensive treatment of ionisation and breakdown in gases and solids.

Some other sections of the book provide background information which is readily available elsewhere. In particular, much of the chapters dealing with small amplitude plasma waves, plasma spectroscopy, incoherent scattering and thermonuclear reactions have been the subject of previous specialist monographs. The main interest of this book, however, is its systematic treatment of the interaction of high intensity, coherent, light with solids, gases and plasmas, and its unifying, pedagogical treatment should therefore be of considerable value to students and younger research workers in the field. The discussion of published experimental work is very well illustrated with line diagrams, but is exhaustively comprehensive; thus the reference list is over 50 pages long. Errors in the text are few and trivial (for example, equation 2.87), and the cross referencing is excellent. It is incorrect to suggest (p54) that laser fusion has introduced a completely new regime of plasma physics; for example, parametric interactions are well known from previous controlled theromonuclear reaction (CTR) work. It is also a pity that there was no discussion of impurity-resonance scattering, nor any pictorial illustration of the growth of hydrodynamic instabilities which have been predicted in two-dimensional laser-compression computer calculations, since these may both have important consequences. Indeed, the degree of spatial symmetry required of alternative laser-compression schemes could well determine the practical feasibility of these approaches to fusion (see Lawrence Livermore Report UCRL-50021-74, p355). With these caveats, the book seems well-balanced, up-to-date, and a pleasure to read. It will certainly become a well-used text in departmental libraries, although a cheaper paperback edition might more realistically suit the pockets of many research students.

I. J. Spalding

Excited states

Excited States in Organic Chemistry. By J. A. Barltrop and J. D. Coyle. Pp. xii+376. (Wiley: London and New York, 1975.) £15.

BEFORE 1965 there were few textbooks in photochemistry but, commencing with the books by Calvert and Pitts and by Turro, the situation has been transformed. Many books are now available and both beginner and expert are well catered for. As a consequence it is necessary for any new book to offer advantages in clarity of presentation, a wide coverage coupled with modernity, appeal to particular groups of chemists, and, not least, a reasonable price, before such a book can be assured of success.

This book is written in a clear, concise style, is adequately cross referenced and develops its material in a systematic fashion. Following an introductory chapter the basic theoretical foundations of the subject are expounded in three chapters (time-independent properties, time-dependent properties and quenching of excited states). The methods specific to photochemistry are then dealt with in detail although the beginner would need to read other books to get a complete presentation of available techniques. A condensed treatment of orbital symmetry and photochemistry follows. The concluding five chapters deal with different chromophores—C=O, C=C, aromatic, nitrogen and saturated—the first three of which present the subject in considerable detail.

Both beginner and expert will profit from reading this authoritative work. The good undergraduate interested in photochemistry would grasp the scope of the subject although he would be more likely to purchase and use one of the smaller and cheaper books which give less detail and a more general coverage. The research student in photochemistry would find the book of considerable use and obtain a perspective for approaching the voluminous literature appearing annually in the Specialist Periodical Reports on Photochemistry. Experienced photochemists including inorganic and physical chemists would benefit from studying this book. It is not as encyclopaedic as Calvert and Pitts but this disadvantage is offset by being up-to-date, at least half of the basic material referenced having appeared since 1966; and in the later chapters dealing with the functional groups three-quarters of the material is new. The misprints are few and almost entirely trivial, with the exception of page 163, where electrocyclic is misprinted as electrolytic. The price is prohibitive for a student, and unfortunately, will limit sales amongst the more specialist audience who will benefit most from reading this book.

Timely review

Point Defects in Solids. Volume 2: *Semiconductors and Molecular Crystals.* Edited by James H. Crawford, Jr, and Lawrence M. Slifkin. Pp. xvi+480. (Plenum: New York and London, 1975.) $45.

THE ever-increasing number of published papers on defects in semiconductors is now vast and so it is invaluable to have timely reviews available for the purpose of coordination and also to act as starting points for newcomers to the field.

The present volume is in reality a collection of six such review articles; these may be subdivided into two groups. The last chapter by Chadwick and Sherwood is concerned primarily with diffusion processes in molecular crystals, a topic which is obviously still in its infancy. In the penultimate chapter by Walton, the effect of defects on macroscopic properties, such as thermal conductivity of various materials is discussed: this is a specialised topic and in this sense is distinct from the earlier chapters.

The first four chapters deal primarily with the effects of radiation on crystals and contain discussions of defect creation, the structure of defects and their effects on the optical and electrical properties of the materials; there is also a chapter on impurity and self-diffusion which are of course not unrelated topics. The styles of these articles vary enormously and their contents also reflect the interests and points of view of the authors. The first by Corbett and Bourgoin is a mixture of sensible speculation, which should provoke further work, and a very comprehensive cataloguing of data, with over 400 references cited. By contrast, chapter four by Watkins on electron spin resonance is completely conservative in its approach, which is perhaps a pity, but its appeal to basic physical ideas rather than to mathematics makes it a superb addition to the literature. The other chapters by Casey and Pearson and by Curtis are of intermediate style, but nevertheless are well written and complete the area being covered.

This volume, although inevitably already somewhat dated, is most welcome, but because of its high price will probably be restricted mainly to libraries.

R. C. Newman

Gauge field theory

Gauge Theories of Weak Interactions. (Cambridge Monographs on Mathematical Physics). By J. C. Taylor. Pp. xv+167. (Cambridge University: Cambridge, London and New York, February 1976.) £10.

FOR more than 25 years quantum electrodynamics (QED) has withstood the rigours of time and increasingly sophisticated experiments, and it remains *the* most successful physical theory yet formulated. Its language is relativistic quantum field theory, and it has always suggested that other interactions of elementary particles should be described in this way. The weak interactions (typical of which is β decay) looked an especially good bet since it was anticipated that a perturbation approach would be even more accurate than QED. All earlier attempts to implement such a programme, however, foundered on the rock of 'renormalisability'. That is to say, the higher order terms in the perturbation series were incalculable because of (unrenormalisable) infinities. The development of the gauge field theories in the last few years has overcome this problem, and at the same time shown how the weak interactions may be unified with QED. This latter feature is necessary in any case, from a practical point of view, since most known weak interactions involve charged particles which interact with each other electromagnetically whether we like it or not.

It is the view of most particle physicists that this renaissance of field theory is here to stay, and this provides the motivation for John Taylor's excellent book. It is not enough to know that one can in principle calculate higher order effects in such theories, one still has to know how to do it; and this requires mathematical techniques not yet in the repertoire of most practising physicists. The technicalities of the quantisation of gauge fields using path-integral formalism and Fadeev–Popov 'ghosts' are all here. There are chapters on the renormalisation of gauge theories using the Ward-Takahashi identities and dimensional regularisation, together with more familiar material on the construction of the Weinberg-Salam model and other general models. I particularly liked the chapters on spontaneous breaking of global and local symmetries.

All of this is lucidly explained, and, even more astonishingly, in only 150 pages. This book is a 'must' for all theoreticians. I anticipate that the material will soon be in postgraduate courses, so perhaps CUP can bring out a student edition. I can pay the book no higher compliment than to say that it carries on where Bjorken and Drell leave off, and at the same high standard.

D. Bailin

Plant diseases

Plant Pathogenesis. Advanced Series in Agricultural Science, Vol. 2. By Harry Wheeler. Pp.x+106. (Springer-Verlag: Berlin, Heidelberg and New York, 1975). DM39; $16.

THE Advanced Series in Agricultural Sciences has as a basic objective the integration of theoretical and technical approaches to agriculture. Volume 2 of the Series deals with pathogenesis, described as the sequence of events that occur during the development of a disease, and is based largely on diseases of higher plants caused by fungi and bacteria. A short chapter on concepts and definitions, important for setting the scene in a book of this type, is followed by a review of mechanisms by which pathogens infect, colonise and damage plants; this and other chapters emphasise the early interactions which are likely to be critical in deciding whether or not disease will develop. The third chapter complements the second by describing the reactions of plants to pathogens and does so under the headings structural, functional and metabolic. There follows an account of disease resistance with emphasis on its induction by pathogens and on the role of phytoalexins. Chapter 5 on the Genetics of Pathogenesis deals briefly with genetics of interactions between pathogens and their hosts but also considers at about the same length the biochemistry of the specificity of these interactions. The last chapter of a few pages speculates on the nature of the response of protoplasts to pathogens. There is a good list of about 200 references and a short index.

The author has ranged over much of the field of physiological plant pathology and has presented interesting and thought-provoking assessments of many different problems which should attract much research by plant pathologists and, it is to be hoped, increasingly by scientists from other disciplines. To get the best from this book the reader needs to know a fair amount about the many and various subjects which are reviewed and discussed. This, however, should not in any way deter the many others who will find in this book a very readable and informative account of most of the basic problems in plant pathology that relate to how microorganisms cause disease in plants or, more often, do not do so.

Messages from the minefield

To attempt to comment on salary levels of scientists is to venture into a minefield. Off in various directions are snares such as historical precedents, parities between government, universities and industry, relations to the cost of living index, and rivalries, even jealousies, between different professions. The appearance of the latest remuneration survey of the Institute of Physics (*Physics Bulletin*, April 1976), however, presents a good opportunity to review the way that physicists are paid. With severe and externally imposed restraint on increases in income this year, and probably next, now is also a good time to look at a scene relatively uncluttered by salary negotiations.

The Institute of Physics has carried out salary surveys for more than 20 years, and although there has been considerable variability in the method of reporting, it is possible to see general trends. The table shows the median salary for Fellows of the Institute (the top grade; roughly 20% of the total membership). Where this figure has not been explicitly published, an attempt has been made to extract it from the statistics available. The median for the top grade may not be the ideal pointer, but it is the only one easily available, and nothing seen in other data gives the impression that it is out of line with other trends.

Date of survey	1951	1953	1956	1960	1964	1967	1971	1974	1976
Median salary of Fellows (£)	1,400	1,550	1,950	2,350	3,300	3,600	4,620	5,850	8,260
Median in 1974 (£)	3,800	3,900	4,300	4,800	6,000	5,800	6,000	5,850	5,550

The table also contains salaries converted to January 1974 levels by use of the cost of living index. Purists will no doubt shudder at the misuse of statistics: no allowance has been made for the progressive nature of income tax, and the cost of living index is only a helpful guide to those whose salaries do not differ too much from the national average. As a result the contrast between the 1950s and the 1970s is probably not as marked as it seems. Nevertheless, two points can be made: that the rewards of being a scientist grew steadily until the mid-1960s, and that since then the rewards have barely held their own.

For the past year or two we have all been rediscovering industry, relearning that the country cannot function without a productive industrial sector, attempting to help industry by increasing university links, and so on. But figures from the survey show how unattractive industrial salaries look in comparison with government and university pay. In 1974 the median salaries for all the institute's membership (not just Fellows) were £3,400 in industry, £4,420 in university, £3,500 in central government. By 1976 industry and university medians had moved roughly with the cost of living to £5,000 and £6,300, while central government had risen all of 70% to £6,000.

A cross-check on these last figures can be found in the most recent remuneration survey of the Institute of Electrical Engineers for January 1976. This confirms that median salaries in central government, the nationalised industries and universities are more than £1,000 higher than those in industry. No doubt there can be bickering over fringe benefits, security of tenure, relative qualifications, pension schemes, and so on, but the message is clear enough: the sector of the economy that is looked upon to solve our present economic woes cannot match the salary rewards that are available elsewhere; and with pay restraint this balance is unlikely to be redressed for some years. Historically, salaries in the three spheres of government, university, and industry have never got so far out of line as this. Does the government realise the consequences, including that of damping mobility out of the public sector?

Concorde's circadian conquest

"BUSINESSMEN interviewed as they disembarked at Heathrow Airport recently after a British Airways Concorde flight from Bahrain had one thing in common—they felt alert without any suggestion of 'jet lag'."

So runs a recent British Airways advertisement for Transatlantic Concorde. The operation is about as meaningful as being assured by the departing clientele of a pub at closing time that they are not suffering from a hangover.

There is no precise definition of what jet lag is, but if you gave those businessmen at Heathrow time to think for a bit they would probably perceive through the haze of Chateau Brane Cantenac '70 that they couldn't know whether they were jet lagged until they had found out whether their internal clocks were waking them up at the witching hour of 3 AM the following morning. And that will happen, Concorde or 707. But no doubt in their haste to get back to their office they would settle for a definition of jet lag as the way they felt on emerging from the plane. Besides, you've got to justify the elevated price by something besides the smoked salmon and peaches in kirsch.

Now all this is as harmless as claiming that a certain dogfood prolongs active life or a certain sauce is 99.46% pure. But wait until the businessmen are being enticed to fly to a day's work in New York and to return to London the same day. British Airways won't be interviewing them at Heathrow about jet lag, because they'll be travel-weary. They'll be rung up the following morning in their office and asked did they wake at an unearthly hour. Of course they didn't—Concorde cuts jet lag either way. □

Coal comfort for Britain?

Allan Piper reports on the fortunes of the British coal industry, reflected in the recent controversial decision to develop the Selby coalfield

Photo: WHO

Coal face

PERHAPS the most important point to be made about the plans to open up the Selby coalfield is that just three years ago any idea that the National Coal Board (NCB) might invest up to £400 milions in a single new venture would probably have been dismissed as economically senseless. In steady decline since the 1950s, the industry seemed by 1973 to be plunging inexorably to extinction, pulled by the ever tightening purse strings of successive governments intractably committed to oil and nuclear power by the strategy laid down in a 1967 White Paper on Fuel Policy. But the hiccough that arrived with the Arab oil crisis forced another look at the shape of coal's future—and the Selby project has become, perhaps deceptively, the banner heading coal's march back to prominence in Britain's energy strategy.

If all goes according to plan, the first Selby coal will arrive at the surface within four years, and by 1985 the new field should provide 10 million tons annually. But while the Selby scheme is ambitious enough itself, its real significance lies in its role as part of a wider "Plan for Coal" developed to boost sagging production levels over the next ten years. Quick to realise the opportunities presented by the fuel price adjustments of recent years, the NCB along with government and union officials formulated the ten year plan back in 1974 in an effort to stabilise and expand the British coal industry.

The aim is to introduce 42 million tons of new capacity by 1985, thus outstripping the decline of exhausted reserves and boosting production from last year's 125 million tons to an annual level of 150 million tons. Though almost half, and possibly more, of the new capacity is expected from new mines such as those on the Selby field, an equally significant amount will be brought out from pits now scheduled for extension and modernisation. And with exploration programmes proving around 500 million tons of new workable deposits each year (some even as far south as the edge of the London Basin), supplies look safe for at least another century at existing extraction rates.

In support of the expansion drive, the NCB has already begun stepping up its programme to introduce new mining equipment and techniques, and mining research is now firmly focused on the development of remotely controlled underground machinery. Initial estimates put the necessary research and development expenditure at £33 millions up to 1980. The increase in mechanisation will not see a reduction in the existing work force: the NCB view is that recruitment must average around 28,000 a year—8,000 a year more than during the cutbacks of the last decade—just to stabilise output levels. By the time target levels are achieved in the mid-1980s the industry should maintain a stable work-force of 250,000, with a hoped-for productivity growth in excess of 4% a year.

The massive investment programme at the heart of the ten year plan was put at an estimated £1,400 millions at 1974 prices, a figure which included £600 millions in new investment. These figures are already being revised to £1,800–£2,000 millions and £1,000 millions respectively because of inflation, and the NCB might even be looking for special subsidies in the future if it cannot raise the money itself. Significantly, though, the coal industry was one of the few areas to escape the heavy spending cuts announced in a recent White Paper on Public Expenditure; NCB borrowing powers have been extended from £700 millions to £1,100 millions under the National Coal Board (Finance) Act, and a further increase to £1,400 millions awaits House of Commons approval. The NCB has also received strong European support through its membership of the European Coal and Steel Community (ECSC). Since Britain joined the EEC in 1973, the Community has approved loans for the NCB totalling £143 millions.

While the new flow of cash is crucial to the revitalisation of the industry, the UK Energy Secretary, Mr Anthony Wedgwood Benn, has not been unmindful of the need for comfortable union-management relationships. He admitted that union thinking influenced his recent decision to reappoint Sir Derek Ezra as NCB Chairman when his present term ends in July, and actually published the text of a letter seeking union advice on new appointments. Ezra is regarded favourably by the unions within the industry; his period of office has so far spanned two major national coal strikes, but he has managed to remain on consistently good terms with them. Last year a deficit of £112 millions was turned round to a profit of £34 millions, and last week Ezra gave estimates that the NCB broke even in 1975–76. His new term will run to 1979, by which time the ten year plan will be well under way.

All of which seems encouraging enough. Certainly with such key issues as finance and industrial relations apparently resolved, the coal industry is anticipating a rosy future, with coal occupying a central role in any long term energy strategy. The large demands of the British steel industry are expected to rise with the next economic upturn, and recent progress in the development of high-grade coking coal may curb future demands for imports. Even more important to the NCB is the judgment that by the mid-1980s nuclear and natural gas resources can between them fulfill considerably less than half of Britain's annual energy requirements of between 400 and 500 million tons coal equivalent. And while much of the shortfall, which could be as high as 370 million tons coal equivalent, will be met by indigenous and imported oil, competitive coal prices, the NCB argues, should ensure demands for its entire output, particularly as cheap imported coal is expected to have become unavailable.

But whether or not that prognosis holds true hinges largely upon the NCB's largest single customer, the Central Electricity Generating Board (CEGB), which last year burned 67 million tons of NCB coal in its power stations (alongside which the South of Scotland Electricity Board consumed a further 4 million tons). And here the critical problem arises. The CEGB is showing a marked reluctance to commit itself to coal-fuelled generating power while oil, gas and nuclear options remain available. One reason seems to be concern at the NCB's record of efficiency. But another is escalating price rises. The NCB, as a member of the ECSC, remains unfettered by national pricing policy, and over the past two years coal prices have rocketed by an alarming 170%; the latest 15% increase adds an estimated £150 millions to the CEGB fuel bill, pushing it up to a colossal £1,600 millions a year. The CEGB chairman, Arthur Hawkins, was sharply critical: "The coal board", he said at a February meeting with Ezra, "might at least have invited its biggest customer to discuss at the highest level the serious implications of the increase, not only for electricity but for coal's prospects in the power station fuel market".

Although taking the point, Ezra's difficulty is that his hands are virtually tied. Confronted with powerful unions, the NCB finds almost half of its production costs are wage bills, while over half of present annual production is won unprofitably from older pits, using outdated machinery and production methods. The increasing volume of reserve stocks piling up at pitheads and power stations around the country adds to the problem: reserves are now standing at 30 million tons, worth £500 millions in realisable income, and costing the coal board £3 a ton in interest on borrowed capital each year. Last year excess sales over running production reduced the stockpiles by less than 10%, but it is a measure of the severity of the situation that before the NCB borrowing ceiling was raised last month, requirements rose above the earlier limit by £75 millions, an excess that had to be provided from government contingency funds.

Success for the NCB plan, then, is to an important extent contingent upon CEGB agreement to convert oil and gas-fired power stations to coal. In proposing an 11 million ton increase in coal burning by the CEGB over the next two years, Ezra has pointed out that a switch from oil and gas to coal could save the electricity industry £3 to £4 on each ton of fuel, and the country £250 millions on the balance of payments. The idea reportedly has the backing of the Department of Energy, but Hawkins has dismissed it as "quite ridiculous" at a time of expenditure cutbacks in the nationalised industries and falling consumer demand (which last year dropped by an estimated 5%). Further, aside from conversion costs, Hawkins has also to consider the heavy national investment in North Sea oil and gas.

As for the less immediate outlook, NCB hopes are similarly overshadowed by CEGB reluctance to order new coal-fuelled power plant. Though the coal-fired, 2,000 MW installation at Drax in Yorkshire has just reached completion, 5 of the 12 remaining installations still under construction in Britain are nuclear powered, and 6 are oil-fired; only the 1,500 MW Aberthaw B in South Wales, due on-line around the end of the decade, is designed to burn coal. In addition, CEGB last month announced that forward ordering plans, already unlikely to favour the NCB, may well be revised downwards following the most recent demand forecasts. These indicate that consumer demand for the winter of 1982–83 will not rise above a peak of 52,000 MW, a surprising 2,000 MW down on last year's forecast for 1981–82, and only around 25% —or 3.5% a year—over current demands.

The CEGB has nonetheless made a couple of moves towards raising its requirement for NCB coal. Imports, which last year totalled 4.5 million tons, are to be cut. Hawkins recently announced that import contracts undertaken during 1973–74 to offset the then prevailing shortage of British reserves are to be run down over the next financial year. And CEGB demand for British coal last year topped the previous year's level by 3 million tons, while oil consumption was cut by almost a third to only 14 million tons coal equivalent. This turn-round indicates that if the price, quality and demand is right, the CEGB's 111 coal-fired installations could burn more coal than at present—in fact the requirement could rise as high as 90 million tons of coal a year, a figure more compatible with the aims of the ten year plan than the existing level of 67 million tons. The present shortfall occurs simply because demand levels above the early morning baseline of 22,000 MW are now met by oil-fired generating power in preference to coal power. But once the Plan for Coal gathers sufficient momentum, increasing productivity and cutting production costs, the NCB could swing that method of priority operation to its own advantage, leapfrogging coal-fired generating power above the oil and nuclear options.

Should that possibility not prove successful, export markets offer little prospect of an easy solution to the glut. In north-western Europe, the only realistic potential outlet, British coal will face competition not only from low-priced North American exports, but also from Polish coal maintained at continually depressed "administered prices" which undercut competition.

The £400 millions Selby project, however, in keeping with the optimistic front it presents to the outside world, remains for the most part unscathed by the wider complications, though critics of the ten year plan may disagree. The Main Barnsley Seam, stretching for 110 square miles beneath the Vale of York and an amenable three or so metres thick, will provide almost half of the new annual output by the mid-1980s. Geological conditions are sufficiently favourable to allow extraction using "drift mining" techniques, involving production through a single sloping tunnel rather than multiple vertical shafts. Production is expected to begin within four years, and when full operational capacity is achieved by the mid-1980s a maximum of 52,000 tons of coal a day will travel by conveyor to the surface, providing the nearby coal-fired power stations at Drax, Eggborough and Ferrybridge with continuous fuel supplies by rail.

Ezra says Selby will produce "the coal which, with North Sea oil and gas, is going to make Britain the only main nation in Europe which will be self-sufficient in energy by the mid-1980s". With the NCB also engaged on large research programmes in pyrolosis and liquefaction techniques, and British and European research efforts continuing in the areas of fluidised bed combustion and coal gasification, the future does seem promising. But there are still uncertainties to be removed if the turn-round is to materialise. □

Coal cutting machine

The threat to peer review

Colin Norman reports from Washington on a series of events which provides a vivid example of the difficulties sometimes encountered by scientists engaged in research on controversial topics

IN A move believed to be without direct precedent, the House of Representatives on April 13 voted to shut off funds for a scientific research project because a powerful Congressman believes the project is scientifically unsound and morally unacceptable. A number of scientists have charged that the vote, if upheld in the Senate, constitutes a worrying challenge to academic freedom.

The project is certainly controversial. An attempt to determine the effects, if any, of marijuana on human sexual responses, it attracted considerable press attention when it was approved last year, and it has stirred up various expressions of moral outrage. Nevertheless, the research has been judged scientifically meritorious by committees of scientists expert in the field, endorsed by the federal government's top advisory committee on drug abuse, and been subjected to a searching inquiry by the government's senior health officials. If Congress does abort the project, the move is certain to be interpreted in the scientific community as political interference with the painstaking peer review process used by virtually every government agency to determine the relative merits of research proposals.

The project is a two-year research effort to be conducted by Dr Harris Rubin, a behavioural scientist at Southern Illinois University Medical School, Carbondale. Rubin's research protocol notes that though there have been many verbal and subjective reports indicating that marijuana has a substantial effect on human sexual behaviour, those effects and the drug's mode of action have not been objectively evaluated. His project involves giving measured doses of marijuana to volunteers and then measuring their physical responses to visual stimuli such as erotic films. Part of the expriment also involves monitoring blood levels of various sex hormones, such as testosterone.

Rubin applied for a grant from NIH for his project in May 1974, and his application was passed on to the National Institute on Drug Abuse (NIDA). It was reviewed for scientific merit by a peer review committee in the usual manner, and two well known behavioural scientists — Dr Joseph Brady of Johns Hopkins University and Dr Jonathan Cole of Columbia University—conducted a site visit and discussed the application with Rubin in January 1975. The peer review committee subsequently approved the project as being scientifically valid, and NIDA decided to fund it in June 1975 with a grant of about $121,000 over two years.

It was then that Rubin's troubles began. A routine announcement of the grant by Southern Illinois University was picked up by the press, several accounts of the project were published, and it was attacked in the *St Louis Globe Democrat* as "tax-paid debauchery". Then Senator William Proxmire, the colourful Senator from Wisconsin who has frequently denounced scientific research which he considers trivial or unsound, took the project in his sights and fired off a press release calling it "one of the most shocking examples of the 'federal love machine' I have ever found". That attracted considerable attention from the media.

While that furore was beginning to break, Rubin applied to the Department of Justice for a grant of immunity from federal prosecution, normally a routine procedure for scientists conducting approved studies with illicit drugs. The application turned out to be far from routine, however, for the Justice department sat on his application for six months, and in January this year it asked the Secretary of the Department of Health, Education and Welfare (of which NIDA is a part) to reevaluate the project and determine whether Rubin is suitably qualified to conduct the research. According to HEW officials, the Justice Department's action is unprecedented.

The reevaluation was carried out on March 11 at a closed meeting attended by the head of the Food and Drug Administration, the Assistant Secretary for Health, the head of NIDA, other government officials and a number of outside scientists—probably the most high-powered committee ever to consider a single grant application. According to HEW sources, the meeting resulted in a recommendation to David Matthews, Secretary of HEW, that the project continue to be supported. Matthews has not yet acted on the recommendation. Similarly, on February 11, the NIDA National Advisory Council, a committee composed of scientists and lay members, unanimously passed a resolution urging Secretary Matthews to support the project.

Rubin has received nearly half of the grant from NIDA, but his project is in limbo until he receives his grant of immunity from the Justice Department.

Meanwhile, Congress entered the picture largely through the work of Representative Robert Michel, the House Republican Whip, who represents Peoria, Illinois. Michel, a powerful member of Congress, is the most senior Republican on the appropriations subcommittee which handles HEW's budget. He has denounced Rubin's project on several occasions, calling it "offensive to the sensibilities of most Americans", and he has twice quizzed HEW officials about it.

Michel made his decisive move against the project by writing into a supplemental appropriations bill containing funds for a number of different agencies, a provision cutting off support for Rubin's research. The bill was passed by the House on April 13 with scarcely anybody noticing Michel's handiwork. The bill is now being considered in the Senate, and a number of scientists have already written to their Senators to ensure that the provision doesn't slip past that body unnoticed.

Though there may indeed be questions about the utility of Rubin's research proposal, the fact is that the project has been endorsed by Rubin's scientific peers, and it has been approved after a painstaking review procedure which is a basic ingredient of federal support for science. If Congress were to overturn the funding decision, it would be an unprecedented step. Dr Joseph Brady, one of the chief reviewers of the project, last week called the House vote "outrageous", and pointed out that the review procedure "was a model of the way the peer review system should and can work".

Dr Robert DuPont, the head of NIDA, noted in a telephone interview last week that "Congress has the perfect right to assert itself in terms of how federal money is spent", but he added that "if Congress is going to reverse the considered judgment of the peer review process, I think it should be extremely cautious about setting a precedent".

As for Rubin, he said that he is "very disappointed" by the House vote, and he argued in a letter sent to several of his colleagues that if the Senate follows suit, "the Congress will be overruling the peer review process and politicians rather than scientists will be determining what specific research projects will be conducted . . . the danger to scientific and academic freedom in this precedent is enormous". ☐

USA

AFTER several months of negotiations richly laced with minor squabbles, key Senators and Congressmen have at last reached agreement on a bill to reestablish a science policy office in the White House. Final Congressional approval of the measure is generally deemed imminent, and the office will probably be off and running by the end of May—nearly three and a half years after Mr Nixon, arguing that he no longer required the services of a full-time science adviser, dismantled the former White House office of Science and Technology.

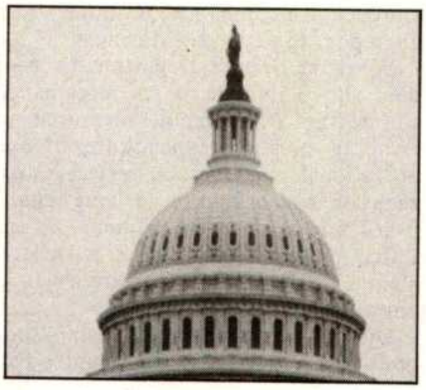
The bill has been in limbo for weeks while Congressional staff members and their bosses have been trying to work out a compromise between three conflicting versions of the legislation—a modest proposal put forward last June by President Ford, a slightly more ambitious measure approved in November by the House and a more substantial bill passed by the Senate in February. A compromise was finally struck in mid-April, and its swift approval by the House and the Senate is virtually assured.

It would establish a small office of Science and Technology Policy (OSTP) in the White House, headed by a director who would also double as the President's Science Adviser, and four associate directors.

Though it has always been assumed that the office would provide advice and assistance to the President and other White House bodies on matters involving science and technology, its exact role and scope have been in dispute. The compromise version of the bill specifies that the Director of OSTP will be a member of the Domestic Council, a top-level White House policy-making body for domestic affairs, and he will also be a statutory adviser to the National Security Council, the powerful defence and foreign policy committee formerly headed by Henry Kissinger. Those roles will at least ensure that the office will have a voice in both civilian and defence policy.

As for budgetary matters, the bill simply requires OSTP to assist the Office of Management and Budget in preparing the Administration's annual budget request, a role which falls far short of the powerful voice in fiscal matters for which many scientists had hoped. The bill does, however, provide two other mechanisms for OSTP to influence budgetary policies. First, it requires the office to prepare a five-year forecast of emerging national problems and provide a set of programme options to every government science agency at the start of each budget cycle. Secondly, it requires OSTP to publish an annual report on federal science and technology, a mechanism which should allow the office to make public its views on the budgetary state of science.

Another important provision in the bill will create a President's Committee on Science and Technology, consisting of between 8 and 14 prominent people, to conduct a two-year survey of the entire federal science and technology enterprise. The President will have the option of making the committee into a permanent body when it has completed its study.



Though the office has yet to be formally established, there is considerable speculation about who President Ford will choose to head OSTP. According to Congressional and Administration sources, there are three potential candidates: Dr Simon Ramo, Vice President of TRW Inc., Dr William O. Baker, President of Bell Labs, and Dr H. Guyford Stever, Director of the National Science Foundation, who now doubles as the President's part-time science adviser.

- The Nuclear Regulatory Commission (NRC) has, as expected, denied a petition seeking a drastic tightening of federal standards governing permissible levels of exposure to plutonium. The petition, filed in February 1974 by the Natural Resources Defense Council (NRDC), was based on the so-called "hot particle" theory which suggests that tiny particles of inhaled plutonium pose a severe health hazard because they lodge in the lung and deliver a prolonged, intense dose of radioactivity to the surrounding tissue. Since present plutonium exposure standards are based on the average dose of radioactivity to the whole lung, rather than to tissue around inhaled particles, the NRDC petition argued that the standards are too lax and should be tightened by a factor of 115,000. The matter has been a subject of considerable debate.

The NRC turned the petition down, and denied NRDC's request for public hearings on the matter, however, because it found that "scientific evidence does not support the technical position upon which the NRDC petition is based". Drawing upon several studies, including reports by the UK Medical Research Council and the former Atomic Energy Commission, the NRC believes that the hot particle theory is flawed in several respects and does not provide a valid basis for establishing exposure standards.

NRDC has also petitioned the Environmental Protection Agency (EPA) with a similar request. EPA is awaiting a report on the hot particle theory from the National Academy of Sciences (expected in about a month) before issuing its reply.

- Following much prodding from Congress and a good deal of agitation from a number of independent expert groups, the Energy Research and Development Administration (ERDA) last week placed increased emphasis on energy conservation in its overall plan for decreasing the United States' dependence on foreign sources of oil. The new emphasis is incorporated in an updated plan for energy research and development, published last week by ERDA, which spells out in some detail the agency's goals and strategies.

The plan, an expanded and revamped version of a document published by ERDA on June 30 last year, ranks the development of technologies to increase energy efficiency and conservation among ERDA's highest priorities. Unveiling the plan at a press conference, Dr Robert C. Seamans, Jr, ERDA's Administrator, said he believed it was "impossible to exaggerate the need and desirability to make more efficient use of energy".

Though the plan isn't very specific about the exact strategies envisaged for conservation, Seamans said that the agency would be putting together "some very significant projects" in the next six months. He added that conservation efforts could save up to five million barrels of oil by 1985.

In other respects, the plan is similar in balance to last year's version, placing heavy emphasis on nuclear energy, coal and production of synthetic oil and gas from coal and shale in the medium term.

As for nuclear power, the plan anticipates that installed capacity will grow from its present level of 39.6 GW to 70–76 GW by 1980, 160–185 GW by 1985, 265–340 GW by 1990 and 450–800 GW by 2000.

AUSTRALIA

Filling the information breach

From Sydney, Peter Pockley looks at Australia's science policy in light of the Science Department's recent Annual Report

SOMEWHAT dated and dented by more recent political and bureaucratic changes, the Annual Report of the Australian Department of Science and Consumer Affairs for the year July 1974 to June 1975 has now surfaced. The most visible dent on the Department is the recent removal of consumer affairs from its title and duties.

Nonetheless, this retrospective report is useful, if only for combining in one list the various activities which, under the now deposed Labor administration, had been brought under the one department. It is, however, as informative to note the omissions from this list as the inclusions, for Labor's Department of Science and Consumer Affairs exercised only partial coverage of the national science scene, a situation unchanged under the new regime. By international comparison, Australia spends in the government sector one of the highest proportions of total research funds (of the order of three-quarters). National figures are not yet available for the year in question, but a conservatively generous estimate puts the Department of Science's proportion of this expenditure (that is, funds directly controlled by the Department) at no higher than a quarter, probably less. At least three-quarters of "in-house" government-financed research was done outside the Department's control.

The most obvious organisation standing beyond the influence of the Department is Australia's colossus of research, CSIRO, with expenditure of $143 million in 1974–75. In company with the newer and smaller statutory bodies, the Anglo-Australian Telescope and the Australian Institute of Marine Science, CSIRO remained responsible directly to the Minister for Science and Consumer Affairs, and not through his Department. (Again, this arrangement did not change with the change in government in December 1975.)

While a lack of mention of CSIRO in the Department's report is strictly correct in legislative terms (indeed, if the proudly independent CSIRO had been mentioned by the Department from which they keep a cool distance, there could have been a row of epic proportions), it means, unfortunately, that the report cannot be treated by local or international readers as representative of the national science scene.

It should also be added that substantial government-financed research and development efforts are also carried on outside the responsibility of the Science Minister. Notable among these are the Australian Atomic Energy Commission, the Bureau of Mineral Resources, and the Weapons and Aeronautical Research Laboratories, who all report to separate Ministers.

What the Science Department report does show, though, is the dominance within the Department, measured in terms of staff and expenditure, of five operational research and service units, each of which had been long established under other Departments before Labor placed them under the Department of Science from December 1972 onwards.

Out of a total of 3,368 established positions, these operational units had 3,097 and the central office 271. The Bureau of Meteorology ($31.2 million), the Patent, Trade Marks and Design Office ($5.7 million), the Antartic Division ($4.5 million), the Analytical Labortories ($2.7 million) and the small Ionospheric Prediction Service ($600,000) accounted for 78% of the Department's overall expenditure of $57.2 million. If $8 million of payments to university researchers by the Australian Research Grants Committee are included, the proportion of these six activities rises to 92%. Through revenue earned, the Patent office was almost entirely self-supporting, and the Bureau of Meteorology earned over a third of its keep, the total revenue of the Department being $17.5 million.

The Department also administers civilian space projects conducted through the operations of three tracking stations for the American NASA. Of the 400 employees in this work, only 40 are Australian public servants; the $11 million cost in 1974–75 was met by NASA.

The Department can point to an apparently modest sum of $2.6 million being spent on general administration. However, the operational units had largely self-contained administrations before their transfer to the Department, and the geographical separation from Canberra of most of them had probably not allowed much in the way of reduced administrative expenses. The Department talks of developing "staff resources without any significant increase in numbers", and of units becoming "more effective as a result of reorganisation". Personalities aside, it is not surprising that friction did develop between the central administration and some of its operational outposts; naturally none of this emerges in the report.

Policy influence

The constraints on an Australian Department Head in writing a report to his Minister are such that only the blandest information on matters of policy and planning is presented. For instance, Sir Hugh Ennor's report does note the formation of the Interim Australian Science and Technology Council (ASTEC) as "an important, but not exclusive, source of advice to the Government". The report adds that "the Department's work will both supplement and complement ASTEC;

AAT change

THE 3.9-metre Anglo-Australian Telescope (AAT) on Siding Spring Mountain, New South Wales, is to have a new Director in September. He is Professor Donald Morton, of Princeton University, and he succeeds Professor E. J. Wampler who left at the end of last month to return to the Lick Observatory in California. Wampler's appointment was for a period of two years ending in October, but by "mutual agreement" he has withdrawn early—mainly because he considered complete his task of seeing the AAT commissioned, but also, it is believed, because he was not completely happy about future prospects for the telescope at a time of economic stringency.

Not that the telescope is lacking funds, according to Professor Vincent Reddish, of the Royal Observatory Edinburgh, who sits on the AAT Board. Its present annual budget is about £1 million, equally financed by the UK and Australia, and, says Reddish, all the indications are that it will continue to be well looked after by the two governments as an important ongoing project.

One of the most interesting aspects of the AAT is the way in which it has been operated hand-in-glove with the UK 48-inch Schmidt Telescope, located a few yards away on the same mountain. The Schmidt is essentially a survey instrument, and on most days AAT astronomers are to be seen in the Schmidt building poring over the most recent plates to find astronomical objects worthy of more detailed examination by the AAT. Much useful work on the spectrometry of faint galaxies, and the dynamics of groups of them, for example, has been done by the AAT in tandem with the Schmidt.

Roger Woodham

in particular, it will act as an agent for ASTEC in obtaining and supplying data in conducting or commissioning studies and in carrying out those liaison and other tasks both within and outside Government that it is favourably placed to undertake". As far as the Department was concerned, the demarcation lines in the highly competitive business of influencing the government are kept nicely fuzzy. All this, of course, may be water under the bridge when the Liberal Government's current review of ASTEC is publicised and implemented.

In support of its own advisory role, the Department has pursued its data collecting activities. The long-running Project SCORE (Survey and Comparison of Research Expenditure) first surveyed expenditure and manpower in Australian research and development for the financial year 1968–69; the results were published in 1972 and 1973. Project SCORE is now reported to be "well underway" on "two-yearly intervals" and using OECD bases for statistics "to be sure that Australian figures may be compared with overseas figures".

The day after the report's period of survey concluded, that is, July 1, 1975, the 555-strong Patent Office was removed from the Department and transferred to the Attorney-General's Department (more recently still it has found another home in Business and Consumer Affairs).

It is easy for outside observers (and most insiders, too) to be bamboozled by the dispersed nature of Australia's scientific organisation. This is not, however, an argument for centralised control, but for at least one government sponsored effort to document in assimilable form the standing and overall progress of science on a national scale. The Science Department's report cannot claim to do this, nor to be fair does it claim to do so. Yet, not many scientists in Australia are more than dimly aware of what is going on in fields outside their own speciality. The interested public and politicians find the task equally tough, although they are helped by some very informative programmes on ABC radio.

The only organisation in Australia which has had the drive and capacity to fill this information breach is the interim ASTEC, but it is still on ice while the government reviews its aims and operations. If, however, ASTEC is allowed by Prime Minister Malcolm Fraser to survive in anything like its form under Labor which would make public reporting central to its functions, then the prospects of the scientific community and general public alike catching and keeping up with the hare of Australian research are quite bright. Or, is it a tortoise? ☐

USSR

Give and take

April, traditionally an auspicious month for Soviet scientists with the announcement of the Lenin Prizes, has this year brought an ominous picture for those out of favour with the establishment: two dissident scientists on trial, continuing harassment and repression of refusniks, and Academician Andrei Sakharov briefly held with his wife in police custody. Vera Rich reports

THE recent "Omsk incident" involving Academician Sakharov marks a new development in the Soviet authorities' campaign against him—the loss of his personal immunity. It happened when Sakharov and his wife Yelena tried to attend the trial of Mustafa Dzhemilev, a young agronomist who has become the leader of the movement for the repatriation of the Crimean Tartars, deported *en masse* to Siberia in 1944.

"Political" trials in the Soviet Union are not normally open to the public, but Sakharov did sometimes manage to enter the courtroom as a friend of the accused—in the case of the mathematician, Dr R. I. Pimenov, in 1970, for example. By 1972, however, when Vladimir Bukovskii was on trial for having sent to the West detailed reports on Soviet misuse of psychiatry for political ends, Sakharov was no longer admitted, protesting instead outside the court. Now he and his wife have been prevented from doing even this.

According to Sakharov, who says two official TASS bulletins on the incident are false, plain-clothes KGB men prevented the friends and relatives of the accused from entering the courtroom, using "rude physical force", directed "in particular" at Sakharov and his wife. In an "immediate reaction" to the "mockery of the feelings of friends and relatives, the mockery of the law, the whole tragic circumstances of this case and other political cases in our country", Sakharov said he hit in the face "one or two KGB men" and a civil policeman who was acting on KGB orders. The Sakharovs were removed to police headquarters, where Sakharov made a statement claiming that the police were acting "on the side of the law-breakers". The next day, the Sakharovs tried once again to protest against the exclusion of the Dzhemilev family from the court, and again were taken to police headquarters.

Sakharov stresses that the civil police treated them "correctly", and says that earlier reports to the contrary were due to a bad telephone connection to Omsk. He denies vehemently that he created a disturbance in the courtroom, as TASS had claimed. This was quite impossible, he says, since "three ranks of KGB men" prevented them even getting near the court. He admits that the possibility of criminal charges against himself is "not excluded".

Sakharov's attempt to focus world attention on the Dzhemilev trial in Omsk, a city closed to foreign journalists, came at the same time as his friend and close associate in the human rights movement, physicist Andrei Tverdokhlebov, faced similar charges of anti-Soviet activity in Moscow. Sakharov felt that the location of this trial in the capital, and the fact that Tverdokhlebov's membership of the illicit Moscow group of Amnesty International makes him a well-known figure, would ensure publicity abroad, whereas the Dzhemilev trial might pass unnoticed without his presence. Tverdokhlebov was sentenced to 5 years' exile; Dzhemilev received 2½ years in a strict regime labour camp.

As for the general position of dissident scientists, this shows little sign of improving. The Kiev seminar for Jewish refusnik scientists, one of the many off-shoots of the original Voronel seminar in Moscow, and led by physicist Vladimir Kislik, has been shut down. Mark Azbel, who now runs the Voronel seminar, has once again been refused a visa for Israel. And Professor Veniamin Fain, one of the very few activists and refusniks to be allowed to continue in his academic career, has now been dismissed from his post at the Institute of Solid State Physics in Moscow.

Sakharov has meanwhile accepted an invitation to become a member of the executive committee of the Campaign Against Psychiatric Abuse (SAPA), the British section of the International Initiating Committee against Misuses of Psychiatry for Political Purposes. ☐

IN BRIEF

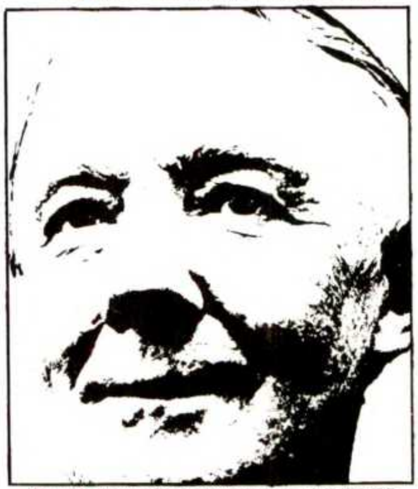
Uranium meetings

The first ever talks between consumers, processors, and producers of uranium have been called to coincide with the annual general meeting of the UK Uranium Institute in London on June 15. The Institute, a "think tank" set up last year by uranium producers, admitted electrical utilities and nuclear fuel reprocessors in January, and at the June meeting representatives are expected from Western Europe, Australia, Japan, North America and South Africa. They will discuss the physical and commercial factors influencing the uranium market and the issues they raise for the industry. In Vienna earlier this month, delegates from 38 states attending an International Symposium on the Exploration of Uranium Ore Deposits, arranged jointly by the International Atomic Energy Agency (IAEA) and the Nuclear Energy Agency (NEA) of the OECD, heard that the discovery rate must increase from around 80,000 short tons a year to nearer half a million by the turn of the century if projected demands are to be met. The IAEA and NEA are now looking at the need for "a more permanent group of experts" to consider the best directions for research and development in exploration techniques.

Indian population measures

In an effort to combat the country's population growth, India's Minister of Health announced earlier this month an increase in the minimum marriage age, from 18 to 21 for men and from 15 to 18 for women. Compulsory national sterilisation will not be introduced for the moment, though individual states will be allowed to enforce their own sterilisation measures for couples with three children. Incentives for voluntary sterilisation will include Government payments to couples of up to 150 rupees (around $17); schemes introducing favourable priorities for jobs, accommodation and loans will be left to individual states. About 8% of federal government aid to states will be directed towards family planning; the amount states will receive will be based on 1971 population figures, as will the number of seats they hold in Parliament. Three states — Maharashtra, Haryana and Punjab—have already drafted legislation for compulsory sterilisation. India's population, estimated at 600 million, could top 1,000 million by the turn of the century if it continues rising at the present rate of 1 million a month.

Zoo celebration



KENNETH MELLANBY

APRIL 29, 1976 is the 150th anniversary of the historic meeting at which Sir Stamford Raffles proposed the formation of the Zoological Society of London, best known to the public because it established the London Zoo. Even then, however, the creation of a menagerie came second to "the advancement of Zoology and Animal Physiology" in the objectives of the society. For the last 150 years the society has continued its scientific work in addition to maintaining the collections of living animals in Regent's Park and, since 1931, at Whipsnade in Bedfordshire.

A visit to a zoo is generally looked upon as a harmless form of recreation, though there are those who voice moral objections to the display of captive animals. In the past, some zoos kept animals in unduly restricted cages, fed them on inadequate diets, and paid scant heed to their welfare. As a result disease was rife and survival short. In addition, populations of rare wild animals were often depleted or exterminated when collectors killed many more than they shipped back to maintain the collections. The Zoological Society of London was, from the first, aware of these dangers, and tried to improve the condition of their animals by studies of their physiology, nutrition and behaviour. Attempts were also made to breed as many as possible to reduce the pressure on the wild stock.

Even in 1877, when the Regent's Park zoo was being planned, efforts were made to house the animals properly: the architect employed by the society, Decimus Burton, divided his efforts between designing the Atheneum Club for the literary and scientific leaders of the period, and creating a house for the giraffes in the zoo. The club has changed little, but standards of animal accommodation have improved considerably.

Zoos are used for systematic teaching of zoology as well as to show visitors the variety of the world's animal life. British children learn about the fauna of other lands, and many Africans see lions and other species seldom visible in their homelands, though recently the opening of zoos in Africa has changed this. Large crowds at the University zoo at Ibadan in Nigeria can admire a healthy pride of African lions, possibly unaware that they derive from a lion denoted by Longleat in Britain and a lioness from Dresden in East Germany.

Scientific meetings started even before the zoo opened its gates. In April 1827 Dr Joseph Brookes lectured to a substantial audience on his dissection of an ostrich. The scientific journals of the society have continued to be published since 1830. Much of the earlier work was anatomical, using the corpses of animals which died, but there have always been studies of diet and behaviour aimed at improving the conditions of the exhibits. However, not every opportunity for research has been exploited: Sir Peter Chalmers Mitchell (best known for his efforts to establish Whipsnade) told me in 1936 how he had been approached by several ageing members of the aristocracy, who asked to be allowed to act as voluntary keepers of the larger mammals, in the belief that this would enhance their virility. It would have been interesting to have assessed the results; the society might even have gained a source of much-needed income!

Since the last war, scientific work has made further progress. The establishment of the Nuffield Institute of Comparative Medicine, the Wellcome Institute of Comparative Physiology and a modern Animal Hospital has provided unique facilities for research. These are well used, but more money will be needed if their potential is to be fully exploited. The society is now in a position to lead the world in work essential to the conservation of the many animals which are increasingly endangered by human population growth, industrialisation and pollution in their homelands. Conservationists and animal lovers need the Society today even more than they did 150 years ago.

Genetics at the OU

SIR,—Since our veracity, objectivity and judgment have been called in question in a letter signed by Professor Pentz (April 8, page 479), which contests the criticism which we made of the genetics course now offered by the Open University, we hope you will allow us to put the record straight.

Much of the letter is polemical in the worst sense ("gratuitous insult", "prejudice", "mere opinion"). It also distorts our letter to mean what it does not say, namely, that we were attacking *all* Open University courses. In fact, we explicitly and specifically criticise the genetics course only.

The charges of falsehood made against us turn on the technicality of what constitutes "the Consultative Committee". The full Committee consisted of two members of the OU Course Team engaged in writing the course (Professors Rose and Jones), Dr C. Butler as Director of the Nuffield Foundation (subsequently replaced by the new Director, John Maddox), Professor H. Kornberg as a Trustee of the Foundation and five geneticists not involved in the writing of the course (Professors Jinks, Lewis, Pritchard, Sang and Dr Kacser). A sixth geneticist, Professor Bodmer, who was initially a member, later resigned.

It was these five geneticists who were actively engaged in meetings with the course team. In many sessions they made some far reaching criticisms and suggestions, including the proposal to reduce the coverage of the course radically (Consultative Committee meeting of October 20, 1975), but these were largely ignored. Professor Rose was the only member of the course team who attended all meetings. How much of our comments reached the rest we have no means of knowing. Eventually, and in despair, the five felt compelled to write a report to the Foundation who had appointed them. This, quite properly, was confidential and could not have included any member of the course team. All other members received a copy. The debating point that they were not the full Committee, appears to have been introduced to conceal the reality of the situation. In a final attempt to improve the course, the Chairman of the Committee and the Director of the Foundation had a meeting with Professor Rose where the substance of our suggestions was discussed with him. The most important ones had, of course, been previously discussed in Committee. None of our major suggestions were accepted by Professor Rose.

The charge of "prejudice" turns out to be that the considered opinions of five geneticists with many years of teaching experience and great interest in teaching methods are set against the reports of some students that Units 1 and 2 were "OK", "very interesting" or "very easy". We are happy to leave this charge to the judgment of our colleagues.

We have gladly given of our time and experience for an enterprise which, at the outset, appeared to us both academically and socially important. In all our endeavours we had, and continue to have, only the welfare of potential students in mind. Because of this we must re-iterate that the students are ill served by the course as it stands. It is too long, too advanced and too detailed for second level part-time students and is inadequately prepared for non-OU Institutions. It would have been irresponsible to have brushed this opinion under the carpet even if our actions caused embarrassment to a member of the OU staff. Furthermore a venture which has absorbed a very large amount of money from a charity and, as we are now informed, an even larger amount of public money, should not be immune from informed criticism. There is nothing sacred about a Genetics Course—even an Open University course—which is being actively promoted for sale to Universities at large.

Yours faithfully,

J. H. SANG

Science and the media in Canada

SIR,—In reading David Spurgeon's account of science and the mass media in Canada (February 5, page 353), I was interested in noting the abrupt injection of subjectivity in the otherwise quite objective summary, represented by the rather plaintive "how would they know?" comment, referring to popular scepticism of newspaper science articles.

I could cite many cases of science reporting in Canadian newspapers, and personal contacts with reporters, where the clear objective has been to overdramatise science stories, frequently through exaggeration, on the admitted grounds of necessity to catch the readers' eyes. Perhaps this is more acute in the case of environmental sciences (one reporter from a large daily wanted a concoction of disgusting material prepared to be photographed as an example of pollution in the Great Lakes).

Consequently, although I share Mr Spurgeon's dismay at the apparently poor job we are doing in informing Canadians of scientific matters, I must express some relief to learn of our sceptical public.

Yours faithfully,

ROBERT K. LANE
Edmonton,
Alberta, Canada

Competition 7

A PRESENT day headline for Charles Darwin's achievement might read "British scientist finds life's secret on tropical island".

A prize of £10 is offered for the best modern headline for any scientific achievement past or present. Inflated claims or deceptive packaging are welcome. The closing date for entries is June 8.

Competition 6 required a rhyming couplet to help familiarise an SI unit. M. Hammerton of Newcastle receives honourable mention for a McGonagall verse, as does P. A. Mohr of Cambridge, Mass., for his brave efforts to keep the Imperial system alive:

The 3,000 metres steeplechase
Is a two miles less one-and-a-twelfth furlongs race.

But the clear winner was John Gribbin of Brighton with:

A Pascal of pressure on top of your head
Is the same push that butter exerts on sliced bread.

news and views

Does the key fit the locks of the past?

from Peter J. Smith

FEW would now disagree with the view that the plate tectonics hypothesis has provided a most successful model of the tectonic activity now taking place at the Earth's surface. Obviously there are still many unresolved problems, not the least of which, as Helwig has demonstrated recently (*Nature*, **260**, 768; 1976), is the clarification of the processes through which the collision of plates is translated into orogeny. Nevertheless, the basic outline is there, and for the time being there is little reason to suppose that the filling in of the detail is more than a matter of practical application, however difficult that might turn out to be. As Le Pichon *et al.* (*Plate Tectonics*, Elsevier, 1973) have pointed out, the supreme advantage of the plate tectonics hypothesis is that "it is predictive and can be tested by measuring relevant parameters."

But the real problems start with the attempt to extrapolate conventional plate tectonics backwards in time. Some of the difficulties are fairly obvious. An important part of the evidence for modern plate activity comes, for example, from the horizontal and vertical distribution of earthquake hypocentres. But there is no way of directly observing past earthquake distributions; ergo, important evidence for past plate activity is unobtainable. Other types of evidence, such as that from oceanic magnetic lineations, are in principle more permanent but in practice of very little help. As everyone now knows, ocean floors have an unfortunate tendency to disappear down subduction zones, destroying most of their history with them. As most constructive ridges and transform faults occur in oceanic crust, the chances of examples of either plate boundary having survived the past 200 million years are remote.

The burden of evidence in favour of the past existence of active plates must therefore rest on the identification of examples of just one of the three types of plate boundary—the consuming margins which have some direct association with continents But in addition to the practical problems, this raises what some would no doubt call a philosophical issue. The successful identification of old subduction zones is (or, in deference to the cynics, should be) rather dependent upon there having actually been subduction zones in the past. Cady (in *Implications of Continental Drift to the Earth Sciences*, Academic Press, 1973) has remarked that not only do "the earmarks of subduction become blurred with time" but they "may be recognised only by those who believe the present to be an invariable key to the past". Thus Le Pichon and his colleagues, whilst appreciating the difficulty in testing models of older plate tectonic processes and being sceptical of attempts to do so, nevertheless claim that "there is no reason to suspect that there has been any change in the major causes of deformation of the earth during the past billion years or so". This is a view commonly expressed and appears to be based on an ingrained reluctance among Earth scientists to question the tenets of uniformitarianism, however vaguely understood. But is it a valid statement? Is there really no cause to suspect?

There is probably little cause for suspicion about the past 200 million years. The difficulties of identifying Mesozoic fossil plate boundaries are far from negligible, but it is at least evident that throughout this period the present continents were drifting, ocean floors were spreading and plates were interacting much as they are now. The most convincing example of a Mesozoic subduction zone is perhaps the Great Valley region of the western United States To the west of the Valley lies the Franciscan Formation, a chaotic mélange apparently deposited on oceanic crust But the Great Valley sequence itself, separated from the Franciscan by a long sharp thrust fault system but spanning the same time interval, is a more orderly succession of miogeosynclinal rocks overriding part of the mélange to the west and resting on continental crust in the east. As Hamilton (*Geol. Soc. Amer. Bull.*, **80**, 2409; 1969). Ernst (*J. geophys. Res*, **75**, 886; 1970) and others have argued, this is a trench-like environment probably representing an ancient site of Pacific plate subduction; and Dickinson (*Rev. Geophys., Space Phys.*, **8**, 813; 1970) has even reconstructed the position of the sloping palaeoseismic zone on the basis of potash values in the Sierra Nevada which stretches to the east.

But in respect of the Palaeozoic and Precambrian, matters may not be even this simple. Piper (*Earth planet. Sci. Lett.*, **28**, 470; 1976 and elsewhere) has shown palaeomagnetically that Africa and North America apparently acted as a single unit from 2,700 billion years ago to the breakup of Pangaea—a conclusion strongly implying, but far from proving, that Pangaea itself existed for at least that period. Morris (private letter), whilst not necessarily disagreeing with Piper's conclusion, believes that both the quality and quantity of palaeomagnetic data are insufficient to prove the case; and McGlynn *et al.* (*Nature*, **255**, 318; 1975) have produced data which seem to refute it. The problems in obtaining reliable palaeomagnetic directions, accurate ages and thus polar wandering paths from Precambrian rocks are well known. Nevertheless, the balance still seems to be in favour of a single supercontinent for at least the 2 billion years before the onset of Wegenerian drift

If this is confirmed it might have some significant implications. The environment represented by a single continent, whether or not surrounded by a spreading ocean floor, is rather different from that represented by a number of continents interspersed by spreading ocean floors. It is by no means certain therefore that plate-tectonic orogenic hypotheses derived from experience of the latter environment (which involves the interaction of rigid plates whose rigidity can be observed) would be directly applicable to the former. Equally, of course, it is by no means certain that such an extrapolation would not be possible. The point is that there is some reason to suspect that there could have been a change in the major causes of deformation with time, even though such a view could be held in some sense to weaken the strict uniformitarian doctrine. In practice, so strong has been the urge to accept uniformitarianism that there has often been a tendency not to debate the rights and wrongs of applying conventional plate-tectonic orogenic models to an alien environment but to change the environment to fit the hypothesis. Hence the invention of pre-Mesozoic intercontinental oceans—for example, the proto-Atlantic Ocean to explain the Palaeozoic Appalachian–Caledonian orogenic belt in terms of continent–continent collision. Presumably this sort of circular argument is partly why Le Pichon *et al.*, despite their previous statement, regard the attempt to explain older geological features in terms of plate tectonics as having "a certain dream-like quality".

The only person I know to have questioned uniformitarianism explicitly is Sutton (see, for example, Sutton, *Geol. Teaching,* **1**(1), 14; 1976, and Sutton and Watson, *Nature,* **247,** 433; 1974) who has modified the sacred doctrine with an element of evolution, chiefly the idea of a gradual increase in crustal rigidity with time. In Sutton's model the present phase of rigid plate activity, which began to develop about 1 billion years ago, was preceded by about 1.5 billion years of activity involving small permanent plates each a few hundred kilometres across. These small plates were aggregated into "a few large continental sheets which were themselves moving as essentially coherent units" and were separated within the sheets by mobile belts. Such a scheme obviously gives ample scope for the existence of intercontinental oceans; but if it were to be modified in terms of a single supercontinent, the interesting question would arise as to the extent to which the internal mobile belts would be flexible enough to allow internal spreading ocean floors to develop. For upon this might depend the validity of extrapolating current orogenic hypotheses to the pre-Mesozoic mountains which undoubtedly exist.

There is evidence both for and against pre-Mesozoic internal oceans. Taking all the 'favourable' evidence together, however, it may be in order to wonder whether the support it is said to give to ancient internal oceans may not also be based on circular reasoning. Broadly, the existence of ancient subduction zones is inferred from the recognition of rock types (such as mélanges and blueschists) characteristic of modern subduction zones But there is no reason in principle why different tectonic environments might not give rise to some similar rock types in different, though perhaps closely related, ways. Orogenic belts in two different environments may be due to causes similar enough to involve the formation of similar rocks, but not necessarily so alike that they need both involve subduction zones and plate collisions. To argue otherwise would surely be to adopt a form of uniformitarianism so strict that it would probably deny the possibility of two different tectonic environments in the first place. ☐

Genetic engineering

by Peter Newmark

A meeting on Genetic Engineering was held at the University of Glasgow on March 22–23, 1976. It was the 2nd Tenovus (Scotland) symposium of the Nucleotide Group of the Chemical and Biochemical Societies.

"GENETIC Engineering" is a fine title by which to attract the maximum attendance to a symposium. It is for some a sinister, for many an exciting prospect; it not only is seen by many molecular biologists as the path to their second coming but is also attracting considerable commercial interest.

Those who made the trip to Glasgow hoping for evidence of their wilder hopes or fears must have come away disappointed, for the meeting illustrated better the potential than the product of the techniques of cloning recombinant DNA.

The only real applications of cloning to be presented were in relation to the study of repetitive gene sequences. That topic was covered by D. D. Brown (Carnegie Institute, Baltimore), S. G. Clarkson (Zurich) and D. Glover (Imperial College, London). They have all been investigating the organisation of the hundreds or thousands of identical copies that exist for certain genes in eukaryotic chromosomes. The study of restriction enzyme fragments of repetitive genes has already made clear the basic organisation of their tandem repeats.

A finer analysis, however, of these naturally "cloned" genes has resulted from the experimental cloning of their restriction enzyme fragments. The availability of cloned fragments facilitates the preparation of heteroduplex DNAs for hybridisation and electron microscopic analysis by gene mappers. Clarkson has been able to place the *Xenopus laevis* gene for methionyl tRNA_{i} within a particular 1,900 base pair sequence. And Glover has discovered that the DNA sequence coding for 28S ribosomal RNA in *Drosophila melanogoster* is sometimes divided into two subunits separated by a non-transcribed spacer.

The most advanced dissection of repetitive gene sequences is that of Brown on the *X laevis* genes for 5S rRNA and 40S rRNA. In each case they are arranged as tandem repeats of a gene sequence and a non-transcribed spacer sequence. The transcribed sequences are all identical whereas the spacers show some variation in length. Their individual lengths are determined by the number of component small subunit sequences included in each spacer In somatic cell rDNA this heterogeneity in length has been localised to two distinct regions of the spacer sequence.

How is this spacer length variation distributed throughout the genome? The cloning of a tetramer fragment of a 5S rRNA repetitive gene has given Brown sufficient starting material to determine whether adjacent spacers have similar lengths They did not. It is therefore most unlikely that the evolution of the tandem genes involved anything like a rolling circle mechanism.

The soundness of that conclusion and of any others drawn from the use of cloned fragments will depend in part on the fidelity with which the initial fragment is copied during cloning H. M. Goodman (University of California, San Francisco) provided experimental assurance that assumptions of fidelity are, in fact, valid. He has cloned mouse mitochondrial DNA using a pSC101 plasmid vector in an *Escherichia coli* host and has compared the original DNA with that recovered after 25 generations of the host. On the basis of various criteria including restriction enzyme fragmentation patterns, electron microscopic contour length determinations and melting curve analysis, the cloned DNA was identical to its ancestor within the limit of detection of one base pair mismatch in 300.

There were two reports in addition to that of H. M Goodman of the cloning of mammalian genes. One was a very brief mention by K Murray (University of Edinburgh) of the cloning of mouse satellite DNA using a phage lambda vector; the other a full presentation by T. Rabbitts (MRC Laboratory of Molecular Biology, Cambridge) of his success in cloning a partial DNA copy of purified rabbit globin mRNA, using a mini-ColEI plasmid vector (see *Nature,* **260,** 221; 1976).

Gene cloning is clearly an established technique. The same cannot be said for the expression of cloned genes, an aim close to the heart of commercial genetic engineers who hope eventually to be able to harvest gene products such as interferon. But in "Will bacteria produce useful proteins from inserted eukaryotic genes?", N. H. Carey (Searle Research) was far from being able to answer his own question and J. Atkins (ICI) was not very much nearer. The latter is working with a phage lambda vector and a K. Murray host, a combination that at least has resulted in the successful translation of cloned prokaryotic genes, for example the production of penicillinase from the *Bacillus licheniformis* gene cloned in *E. coli.*

Another example of successful functioning, this time without translation of a cloned gene came from H M. Goodman. In a futuristic vein he presented evidence that it was possible to insert into the PM9 plasmid a chemically synthesised, double-stranded, 21 base pair DNA sequence of the *lac* operator. Transfection of *E. coli* with that recombinant DNA resulted in the constitutive production of β-galactosidase by some cells. The conclusion is that the plasmid, replicated to the extent of about 30 copies per cell, provided enough cloned copies of the *lac* operator to bind the cell's six repressor molecules.

Many of the speakers paid tribute to the technological contributions of E. Southern (University of Edinburgh) to their own work. E. Southern himself described both his "gene machine"—a high capacity, preparative agarose gel apparatus allowing 30-fold purification of restricton enzyme fragments—and his transfer technique. The latter technique involves the transfer of DNA fragments, banded in agarose gels, to cellulose nitrate filters on which they can be identified by hybridisation techniques.

Tribute should also be paid to N. M Wilkie (University of Glasgow) who told of his mapping of the herpes virus genome. By admitting his desire to clone herpes fragments he provoked a discussion on the hazards of cloning that had threatened never to surface. No amount of argument, however, could answer D. D. Brown's question of whether the cloned fragments of the herpes gene were any more hazardous than the infectious virus itself, and if not why prohibit the cloning? That particular problem is one of assessing the unpredictable and improbable hazards of cloned fragments against a known enemy. For the moment the fear of the unknown prevails. ☐

A hundred years ago

Mr. Tomlinson's remarks on safety-matches in Nature, vol. xiii, p. 469, reminded me that, not long ago I accidentally kindled one of those matches by rubbing it on the edge of a Wedgwood-ware mortar. This material appears even better adapted than those mentioned by Mr. Tomlinson for igniting such matches, and I found that a common earthenware dish (glazed inside) answered the same purpose admirably I tried to ascertain the degree of certainty with which a safety-match could be kindled by friction against these two materials, and was surprised to find that they are little inferior in this respect to amorphous phosphorus itself

from *Nature*, **13**, 512; April 27, 1876

Fossilised fury

from Barry Cox

Analyses of the mechanical adaptations of skeletons for movement and support, or of teeth for different kinds of diet, are comparatively simple. The interpretation of other structures, once used in the intraspecific social interactions of extinct animals, is far more difficult. Even in modern mammals, such a basic analysis as that of Geist on the evolution and use of horns is still only 10 years old. Where such living analogues are available, vertebrate palaeontologists are using these to explain some structures found in extinct animals, and are using similar techniques to explain other, more bizarre structures which find no obvious parallels in the world today.

In fact, Davitashvili's book *The Theory of Sexual Selection* (1961) included many suggestions as to the possible functions of unusual structures in fossil reptiles, but few non-Russian workers have read it. Some of his ideas have been independently put forward by other workers: for example, Galton (*J. Paleont*, **45**, 40; 1971) has suggested that the greatly thickened skull roof of the pachycephalosaurian dinosaurs was correlated with the use of the head in pushing and ramming during intraspecific combat, like that seen today in mountain sheep.

Geist himself suggested a similar function for the thickened heads of the herbivorous dinocephalian mammal-like reptiles, and Barghusen (*Paleobiology*, **1**, 295; 1975) has now convincingly shown that many other features of their skulls support this interpretation. Strong arches of bone transmit the impact force from the dorsal surface of the head to the occipital condyle. The line of action of this force also passes very close to this condyle, so reducing the torque that such blows would have produced at that joint. Barghusen also extends this explanation to the carnivorous dinocephalians, suggesting that, as in living suids, head butting and shoving allowed combat while reducing the danger of mutual injury from the massive incisor and canine teeth.

Geist (1966) clearly demonstrated that the primary use of the horns of many living herbivores is for intraspecific mating combat or the defence of territory, rather than for defence against predators. Farlow and Dodson (*Evolution*, **29**, 353; 1975) have now used this approach to analyse the horns and frills of the ceratopsian dinosaurs. They suggest that the most primitive ceratopsians, such as *Protoceratops*, used their small nasal horn for lateral blows against the flanks of their opponents, and used the bony frill that extended upwards and backwards from the skull as a visual dominance rank display structure, like the antlers of deer. Some later ceratopsians had a long frill and paired, diverging horns. Farlow and Dodson suggest that the frill would have been prominently displayed when these animals lowered their heads, and that the horns of rivals would have interlocked, leading to a trial of strength—again as in deer. Other ceratopsians, which had unpaired nasal horns and a short frill, they compare with rhinos, in which there is less display, the horns do not interlock, and injury is more frequent.

The strange cranial specialisations of the hadrosaurian dinosaurs have long been a fascinating problem, for they are unlike any structures found in living animals. In some, the bones of the nasal region form solid crests or humps, or are excavated around the nostrils; in others, these bones form elongated crests enclosing the nasal passages. Davitashvili originally suggested that the solid crests or lumps were combat structures and that the hollow elongate crests functioned as species recognition signals in courtship both visually and, by acting as resonating chambers, also audibly (as earlier suggested by Wiman).

Hopson (*Paleobiology*, **1**, 21; 1975) has now examined the implications of these ideas. He points out that if they are correct, various predictions should be fulfilled. For instance, as would be expected, the shape of the crest, being the result of independent selection for behavioural functions, is not merely a reflection of the size and shape of the internal cavity. The crests also appear to be dimorphic; otherwise identical skulls show variation in the size of the crest, and presumably belong to different sexes, while different sexes bear characteristically different crests. These species recognition features also, as would be predicted, are better developed in those faunas which contain a greater number of species of hadrosaur.

According to Hopson, the excavations around the nostrils of some hadrosaurs were filled with soft tissue, which could be inflated as a display structure and might also act as a resonator (as in elephant seals). He believes that the function of the elongate, hollow nasal tubes of other hadrosaurs was to provide a permanently dilated resonating system while at the same time providing a visual threat display.

The work of Geist and Davitashvili has provided a useful new approach for vertebrate palaeontologists. Though they cannot employ the experimental or observational methods in testing such hypotheses on fossil material, such techniques as Barghusen's analyses of associated structural adaptations, or Hopson's prediction-testing method, can provide adequate alternatives, and it is to be hoped that yet more fossil humps and bumps will find a function in the future. ☐

Liposomes to lysosomes

from a Correspondent

Now that many of the enzyme deficiences which cause the lysosomal storage diseases are known, efforts are increasingly being directed towards finding methods of therapy. One obvious approach is to replace the defective or absent enzyme (see for example, *Enzyme therapy in lysosomal storage diseases*, edit by Tager *et al.*, North Holland/American Elsevier, 1974). These diseases seem to be particularly suitable candidates for enzyme replacement therapy because extracellular macromolecules and particles are taken up by the process of endocytosis (phagocytosis) into the lysosomal system. Thus enzymes supplied (to the blood stream) may be expected automatically to reach the intracellular location where they are needed. They still, however, have to be directed to the particular tissue or tissues where most lysosomal storage occurs and these (brain and muscle, for example) often do not carry out much endocytosis. In order to remove the substances that have already accumulated and to maintain the corrected condition a regular supply of enzyme is required. Immunological complications arise from repeated injection of foreign antigens (either the enzyme itself or other substances copurified with it).

The idea of injecting enzyme entrapped in microvesicles, gel particles or red cell ghosts has recently been investigated A non-antigenic vesicle would not only prevent the enzyme from eliciting an immunological response but would protect it from degradation before it reaches the required site. Liposomes, which are synthetic vesicles made of concentric bilayers of lipids alternating with aqueous compartments in which the enzyme can be carried seem to be useful vehicles because they are non-antigenic and biodegradable and their dimensions and constituent lipids can be adjusted to suit requirements. Attempts are now being made to direct liposomes to target organs by coating them with substances which are known to have an affinity for and (or) be taken up by a particular tissue.

In a recent paper Cohen *et al.* (*Biochemistry*, **15**, 452; 1976) describe *in vitro* experiments on the entrappment of N-acetyl hexosaminidase A (the enzyme deficient in Tay-Sachs disease) by liposomes and the uptake of these liposomes by the polymorphonuclear leukocytes of a patient with Tay-Sachs disease. Selective endocytosis was encouraged by coating the liposomes with aggregated immunoglobulin (IgG), a successful idea based on the known uptake of immune complexes by polymorphonuclear leukocytes (Weissman *et al.*, *J. exp. Med.*, **134**, 149s; 1971). The liposomes were shown to be taken up by the lysosomes and N-acetyl hexosaminidase A was detected in the 'corrected' cells.

This type of *in vitro* experiment merits further study, not only to investigate the fate of the entrapped enzyme and the liposomal material, but also the breakdown of the accumulated substrate. The question of access of the liposome-entrapped enzyme to the 'residual bodies' of the lysosomal system where much of the stored material is found, needs to be resolved. Furthermore, as it is known that activity of N-acetyl hexosaminidase towards the natural substrate, the ganglioside GM_2 is lost on purification (Srivastava *et al.*, *J biol. Chem.*, **249**, 2043; 1974) it will be of great interest to see whether activity towards the natural substrate can be restored by replacing the purified enzyme within the cell.

While few animal models are available for the study of these diseases, *in vitro* experiments of this kind are clearly useful model systems. At the same time an investigation into the safety of the injected ingredients is of paramount importance and this can be done most conveniently using experimental animals. The release of lysosomal acid hydrolases which seems to occur parallel with the endocytotic uptake is a side effect that should be considered further. It is of interest to note that some of the pharmacological effects of liposomes are currently being investigated (Bruni *et al*, *Nature*, **260**, 333; 1976).

Successful treatment of Tay-Sachs disease as well as other infantile diseases with neurological involvement seems, however, unlikely to be practicable. The difficulty of penetrating the blood-brain barrier, a prerequisite for removing accumulated substrate from the brain is problem enough. Also substantial accumulation and possibly irreversible damage have already occurred as early as 16 weeks gestation (Schneck *et al.*, *Pediatrics*, **49**, 342; 1972). Treatment of juvenile and adult onset diseases (such as Fabry's disease) seems on the other hand to be a more hopeful and justifiable proposition. ☐

Triton interactions

from P. E. Hodgson

THERE have been rather few studies of the interaction of tritons with nuclei, mainly because tritons are highly radioactive, with a half-life of about 12 years. Very stringent safety precautions have to be enforced, so work with tritons is usually done in Government laboratories. A series of measurements of the differential cross sections for the elastic scattering of tritons by nuclei was made some years ago at Aldermaston, and analysed to give triton optical model potentials. There were hardly any measurements of triton polarisation and these were of low accuracy, so very little was known about the spin-orbit term in the triton optical potential.

Recently a polarised-triton source has been installed on the Los Alamos Scientific Laboratory Tandem Van de Graaff accelerator, and this has made possible new measurements of triton elastic scattering of a higher accuracy than ever before. The Los Alamos group have measured the differential cross sections and polarisations for tritons elastically scattered from several nuclei, and analysed the results with the optical model (*Phys. Rev. Lett.*, **35**, 1623, 1975).

It is possible to calculate the triton optical potential by averaging the known nucleon–nucleus interaction over the three nucleons comprising the triton. This folding model, as it is called, has already been used successfully to calculate the optical potentials for deuterons, helions, and alpha particles, so it is important to test it for tritons as well.

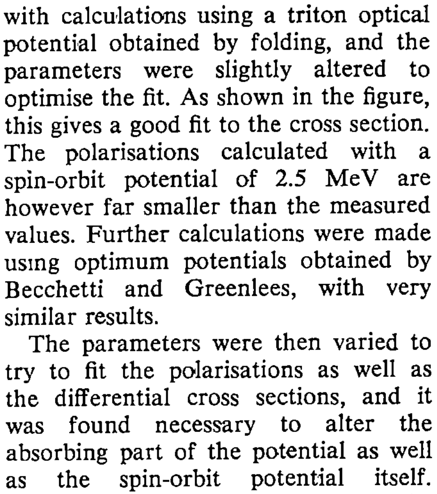
The folding model gives for tritons an optical potential that is about three times as deep as the nucleon optical potential, has about the same radius and is slightly more diffuse in the surface region. The two neutrons in the triton are anti-aligned, so that the spin-orbit force between a triton and a nucleus is the same as that between a nucleon and a nucleus.

Now the spin-orbit force is written as $V_{so}(r)\mathbf{L}\sigma$, where σ is the spin of the projectile and **L** the relative angular momentum between the projectile and the target. For the same incident velocity this angular momentum is three times greater for a triton than for a nucleon, so we expect the spin-orbit potential depth to be one-third the nucleon value to leave the whole potential the same. Since the depth of the nucleon spin-orbit potential for nucleons is about 6 MeV we expect a value of about 2 MeV for the triton spin-orbit potential.

To test this prediction, the differential cross sections were first compared with calculations using a triton optical potential obtained by folding, and the parameters were slightly altered to optimise the fit. As shown in the figure, this gives a good fit to the cross section. The polarisations calculated with a spin-orbit potential of 2.5 MeV are however far smaller than the measured values. Further calculations were made using optimum potentials obtained by Becchetti and Greenlees, with very similar results.

The parameters were then varied to try to fit the polarisations as well as the differential cross sections, and it was found necessary to alter the absorbing part of the potential as well as the spin-orbit potential itself. Potentials were found that fit the polarisations very well, but they have spin-orbit depths of 6 MeV, which is much greater than that given by the folding models.

The new data can therefore be successfully analysed by the optical model, but the strength of the spin-orbit potential is unexpectedly high, and poses a challenging theoretical problem. □



Polarisations (top) and differential cross-sections (bottom) for the elastic scattering of 15 MeV tritons by ^{60}Ni and ^{90}Zr compared with optical model calculations with a folding model potential (dashed lines) and with a Becchetti–Greenlees potential (full lines). Both potentials fit the differential cross-sections quite well, but give polarisations that are far too small.

Disturbed habitats

from Peter D. Moore

ONE of the basic aims of ecological research is the generation of theoretical models on the basis of which predictions can be made. The complexity of interactions in any ecological system make this a difficult task, but it is a particularly necessary one especially where a basis is required for the formulation of an informed management programme for a given habitat. As a consequence of this need, there has been a noticeable swing in ecological research in recent years away from the traditional study of 'natural' ecosystems to an unashamed interest in those habitats which have been subjected to some disturbance or perturbation at the hands, or feet, of man.

A good example is that of sand dune habitats, where the bulk of ecological research interest is no longer focused on the general course of successional process, but has become concentrated on the effects of trampling upon soils and vegetation. Some recent work in this field by Liddle and Grieg-Smith (*J. appl. Ecol.*, **12**, 893 and 909; 1975) has involved both descriptive and experimental studies on the Abeffraw sand dunes in Anglesey.

Examination of soils revealed that several changes occur with trampling. Trampled soils were found to have increased in their bulk density and, as might be predicted, the effect of a car was considerably more severe than the passage of a human being, the density being increased by a factor of about 30% more after a car has passed than after a man. Soil compaction was associated with higher water content, which could favour certain species sensitive to water stress in this arid environment, but the anaerobic nature of such soils would not encourage extensive root growth by most species.

Examination of the vegetation from transects across paths showed that although species number decreased towards the path centre, diversity remained fairly constant This suggests that loss in richness is accompanied by an increase in evenness of apportionment of biomass between species; this was probably caused by reduction in dominance with increased trampling pressure. Other observations show a fall in total biomass and an increase in the proportion of that biomass belonging to monocotyledenous species as trampling increases.

Unfortunately the vegetation data suffer from the disadvantage of having been gathered in June, when most of the winter annual species (mainly dicotyledons) would have already flowered and died. Since many of these species flourish under disturbed conditions, especially if sand is laid bare, they are likely to be an important winter and spring component of the path flora. Liddle and Grieg-Smith suggest that monocot : dicot ratio could prove a simple and useful index of trampling intensity, but seasonal factors need to be considered since there will be a greater proportion of dicots in winter.

Liddle (*Biol. Conserv.*, **8**, 251; 1975) has attempted to generalise yet further concerning the vulnerability of vegetation to trampling, on the basis of his sand dune data and further information derived from other habitats. He demonstrates a linear relationship between the logarithm of the number of people needed to pass along a linear path through a given vegetation type in order to reduce its biomass or cover by half, and the logarithm of the recorded primary productivity of that vegetation type. This relationship is not surprising, since more productive vegetation may be expected to regrow after trampling and so recover its former biomass more quickly. Liddle also considers that mature ecosystems are more resistant to trampling than early successional ones because they are more productive. This is not consistent with his own data, however, which show that short turf grassland containing such species as *Festuca rubra*, *Bellis perennis*, and *Poa pratensis* are particularly resistant to trampling yet are not mature in the successional sense, unless one regards the path community as a 'trampling climax', in which case the argument becomes a semantic one. The productivity/trampling resistance relationship may be genuine, but there is a danger of confusing net and gross ecosystem production when making successional inferences. Net ecosystem production does not rise during the early stages of succession, but then falls to zero at climax. Some of the most productive plant species are in fact found in immature ecosystems. It is therefore unwise to state that mature ecosystems are more productive, and therefore, more resistant to trampling.

The development of predictive models, or even the derivation of simple indices for the monitoring of man-induced changes is still some way off. But if Liddle's ideas on productivity are sufficiently compacted to hold water then we should be able to increase an ecosystem's tolerance to trampling simply by fertilising it. □

Variability of AO 0235+164 at radio, optical, and infrared wavelengths

The most recent outburst of the BL Lacertae object AO 0235+164, in November 1975, was particularly large and built up very quickly. These three papers present measurements made at radio, optical and infrared wavelengths, and discuss the extent to which the emitting regions in each case are associated.

Variability of AO 0235 + 164 at 2.8 cm.

THE radio source AO 0235+164 was discovered by Hazard and Sutton during lunar occultation observations at the Arecibo Observatory[1]. Spinrad and Smith[2] classified the optical object as of the BL Lacertae type. It is a moderately bright variable stellar object with an off-centre nebular extension to the south. In this issue of *Nature* Rieke *et al.*[3] report extensive optical observations which demonstrate the extraordinary nature of this object. The recent behaviour of the source at radio wavelengths is described here and in an accompanying paper by Ledden *et al.*[4].

AO 0235+164 was added to the list of sources observed regularly in the variable source programme at the Algonquin Radio Observatory[5] (ARO) in October 1972. Since then its flux density has been measured about once a month. The results are given in Fig. 1 and Table 1. The methods and errors of observation have been discussed by Medd *et al.*[5].

There have been at least three major outbursts in three years, the last of which, peaking in November 1975, had an extremely large and rapid increase. The ratio of maximum (7.6 Jy) to minimum (0.6 Jy) flux density observed for this source is ~ 12. This ratio is by far the largest we have observed for any source at 2.8 cm, the next largest being ~ 6 for BL Lac.

Fig. 1 The flux density of AO 0235+164 at 2.8 cm since November 1972.

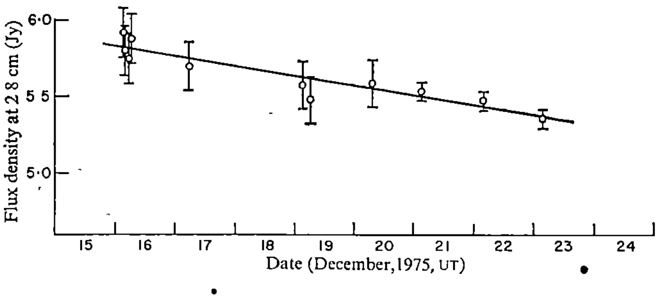
Such behaviour seems typical of BL Lac objects. The majority of other BL Lac objects in the ARO programme also show rapid variations (time scales $\lesssim 1$ yr) and $S_{\max}/S_{\min}$ ratios in excess of 2 (for example, PKS0048−09, DA55, OJ287, OT081, BL Lac) though a few do not (PKS0735+17, PKS1514−24) (B. H. Andrew, G. A. Harvey and W. J. Medd, in preparation).

Measurements of the flux density of AO 0235+164 during the period December 16–23, 1975 (Fig. 2) showed no evidence of daily variations > 0.1 Jy, though variations of 1 or 2 Jy have already been detected on this time scale in both OJ 287 (ref. 6) and BL Lac (ref. 7) on several occasions.

Fig. 2 The flux density of AO 0235+164 at 2.8 cm from December 16–23, 1975. There is no evidence for rapid variations superimposed on the gradual decay of the event of November 1975.



The Algonquin Radio Observatory is operated by the NRC of Canada. We thank Dr A. E. Neill for drawing this source to our attention, Drs P. C. Gregory and W. H. McCutcheon for making several of the observations in December 1975, and Dr P. A. Feldman for an observation in November 1975.

Radio spectrum of the major outburst in the BL Lacertae object AO 0235+164

THIS paper presents an analysis of the evolution of the radio emission of AO 0235+164 during the recent large outburst which coincided with the optical and infrared event reported by Kinman and Rieke[1]. The event seems to be the clearest case to date of a correlated radio and optical outburst. Spinrad and Smith[2] suggested that AO 0235+164 is a red BL Lacertae object and noted that it is a radio and optical variable. Two smaller radio outbursts have been observed since 1972.8 by MacLeod *et al.*[13] and, based on their data and that of J. C. Webber (private communication), the quiescent flux density level of the source at frequencies > 1 GHz is < 1 Jy (1×10^{-26} W m^{-2} Hz^{-1}). The recent event described here offers an unusual opportunity to study an isolated outburst because its amplitude was much larger than the quiescent flux level, good coverage in time at two radio frequencies was obtained, and simultaneous observations over a wide range of radio, infrared, and optical frequencies were made.

The radio flux density data are presented in Tables 1 and 2. The measurement at 2.7 GHz was made with the 300-foot antenna of the National Radio Astronomy Observatory. Observations of flux density and linear polarisation at 4.9, 8.0 and 14.5 GHz were made with the University of Michigan 85-foot paraboloid using a previously described technique[3]. The measurements at 31.4 and 85.2 GHz were made with the 36-foot antenna of the NRAO as part of a millimetre wave variable-source programme being conducted by Hobbs and Dent. Included in Table 2 are a flux density measurement at 5 GHz made with the NRAO 300-foot antenna by J. W. Warner and J. H. Black (private communication) and the average of observations on two days at 90 GHz by B. J. Wills[4].

The characteristics of the observed radio radiation are consistent with the synchrotron radiation process. The emission extended over a broad range of frequencies, and the source was linearly polarised during the outburst by up to 3% at both 8 and

* Observations made with University of Michigan 85-foot antenna.

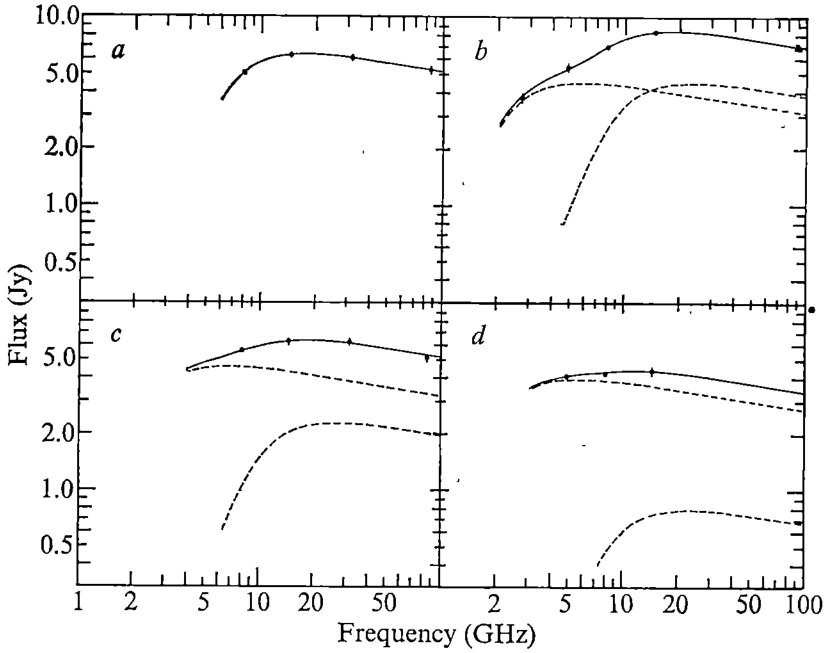

Fig. 2 Spectrum of AO 0235+164 at four epochs: *a*, October 9, 1975; *b*, November 18, 1975; *c*, December 10, 1975; and *d*, January 10, 1976. The solid curves were fitted to the data by summing the two self-absorbed homogeneous synchrotron source spectra shown as dashed lines. The values shown at 8.0 and 14.5 GHz are interpolations of the data shown in Fig. 1. In *b* the 5-GHz data point is an average of two measurements made on November 4 and November 24, 1975 and the 90-GHz data point is an average of measurements made on November 20 and November 21, 1975.

14.5 GHz and to a higher degree at optical frequencies[4]. A preliminary analysis of our linear-polarisation data indicates no significant difference between the observed polarisation position angles at 8 and 14.5 GHz, which is consistent with the hypothesis that there is no Faraday rotation within the source. The polarisation position angle at 14.5 GHz during early October 1975 was 162±8° which agrees, within our error, with the polarisation position angle observed at optical wavelengths by Kinman[4] on October 3, 1975. This agreement certainly suggests that the radio and optical radiation originated in regions having the same magnetic-field orientations, but the much lower degree of polarisation at 14.5 GHz (2.2±0.6%) indicates that the magnetic field in the radio-emitting region is less well ordered. These polarisation data are evidence of a direct association between the optical and radio-emitting regions.

The time dependence of the radio outburst at 8.0 and 14.5 GHz is shown in Fig. 1. Before the maximum in mid November the fractional rate of increase was the same ($1.7\%\,d^{-1}$) at the two frequencies. The maximum at 14.5 GHz seemed to occur on November 8 which was ~ 6 d before the apparent maximum at 8.0 GHz. Such a delay is qualitatively consistent with expanding synchrotron-source models, but the observed ratio of 1.2 for the flux densities at maxima is significantly less than the ratio of 2.0 predicted by the instantaneous injection model[5]. The observed behaviour of the flux density at the two frequencies could be explained by either a prolonged injection or an acceleration of radiating particles from August through mid November 1975 (ref. 6). The complex light curve at infrared and optical wavelengths also reached a maximum in mid November[4] and appears to be direct evidence of just such a prolonged injection.

The observed radio spectra of the source at four epochs are displayed in Fig. 2. The most striking feature of three of the spectra is the broad low frequency turnover which cannot be fitted by a single homogeneous, self-absorbed synchrotron emitting region but which is characteristic of inhomogeneous synchrotron sources[7]. As the simplest representation of the spectrum of an inhomogeneous source, we have summed the spectra (shown as dashed lines) of two homogeneous emitting regions which become self-absorbed at different frequencies. The progressive flattening of the spectrum at <14.5 GHz after the maximum in mid November (see Fig. 1) is consistent with the turnover progressing towards lower frequencies. This phenomenon is illustrated by the systematic decrease in the amplitude of the high frequency spectral component in Figs 2*c* and 2*d*. Above 30 GHz the source was completely transparent during the period of observation, and our data are consistent with the spectral index α remaining constant at $\alpha = -0.15$. The fact that the source was transparent before reaching maximum is inconsistent with instantaneous-injection expanding source models. It requires that the injection or acceleration of the radiating particles was prolonged and that energy was supplied to the radiating particles more rapidly than it was lost due to expansion of the emitting region. Synchrotron and inverse Compton energy losses seem to have been unimportant for particles radiating at < 100 GHz, as there was no significant steepening of the spectrum with time.

An extrapolation of the radio spectrum in mid November predicts a $\lambda = 20$ μm flux density of 3 Jy compared with an observed flux of 1 Jy (ref. 4). The continuity between the radio and infrared fluxes suggests that the emission over the entire spectrum is produced by synchrotron radiation. The observed spectral index of -1.2 in the infrared and -3.8 at optical wavelengths[2,4] indicates that the synchrotron emission cuts off in the latter spectral region.

A quantitative analysis of the observed emission places additional constraints on models for the source because of the apparent high brightness temperature implied by the rapidity of the variations. Based on the observed fractional rate of change of the flux density, the apparent radius of the source must be $\lesssim 100$ light d. Two absorption line redshift systems, with $z = 0.524$ and $z = 0.851$, have been observed in the optical spectrum[4]. The larger redshift would correspond to a cosmological distance of $\sim 6\times10^9$ pc. This distance and apparent physical size yields an angular diameter of 2×10^{-5} arc s and implies an apparent source brightness temperature of $T_b \simeq 10^{15}$ K at 8 GHz. Such a high intensity would result in the inverse Compton process[8,9] producing a much larger flux of infrared and shorter wavelength radiation than was observed. The observed maximum flux density in the optical B band of 3.7×10^{-3} Jy (ref. 4) can be used to set an upper limit on the radio brightness temperature[10] of $\sim10^{12}$ K at 8.0 GHz. The disparity between this upper limit and the apparent observed brightness temperature is eliminated if the source expands with a relativistic velocity[10,11] or if it is much closer than the cosmological distances associated with the observed redshifts. An expansion velocity corresponding to a Lorentz factor of ~ 10 is sufficient to reduce the brightness temperature in the reference frame of the emitting region to $< 10^{12}$ K and would make the inverse Compton process energetically unimportant in the source. A relativistic expansion of the source would also produce a broadening in the low-frequency self absorption turnover of the spectrum[12] which is qualitatively consistent with our observed radio spectra of AO 0235+164.

We thank R. W. Hobbs, T. J. Balonek, J. H. Black, J. W. Warner and J. C. Webber for allowing us to use their unpublished data; F. T. Haddock, T. D. Kinman, G. H. Rieke and B. J. Wills for discussions; T. V. Seling, the staff of the University of Michigan RAO and the staff of the NRAO for making these observations possible. The NRAO is operated by Associated Universities, Inc., under contract with the NSF. This research was supported in part by grants from the NSF.

Photometric and spectroscopic observations of the BL Lacertae object AO 0235+164

BL LACERTAE objects pose, in extreme form, the question of the nature of the most energetic extragalactic sources. They exhibit rapid variability over a large dynamic range, large and variable intrinsic polarisation, and high luminosity, a combination that is very difficult to reconcile with current physical theory. In this paper, we confirm that AO 0235+164 is a BL Lacertae object with one absorption-line redshift at $z = 0.524$ and a probable one at $z = 0.852$. Photometry between 0.36 and 21 μm and at 90 and 140 GHz showed a peak luminosity in November 1975 comparable with the most luminous QSOs.

Extensive studies in the optical and radio spectral regions have documented the variations in flux and polarisation for a number of these sources[1,2]. The available infrared observations are far less complete, even though BL Lac-type objects emit a large, frequently dominant, portion of their energy in this spectral region. Coordinated programmes to study the behaviour of these sources in all three spectral regions are needed.

Their lack of emission lines has made it difficult even to estimate the distances of these sources. Two absorption lines identified as the Mg II doublet redshifted by $z = 0.424$ have, however, been found in the spectrum of one of these objects (PKS0735+178) (ref. 3). In addition, BL Lac itself and some probably similar objects (1101+38, 1652+39; ref. 2) have surrounding nebulosity which shows absorption lines at redshifts of $z < 0.1$.

AO 0235+164 is a newly discovered member of this class of object. Based on the coincidence of precise optical and radio positions, it was identified by Argue, Kenworthy, and Stewart[4] with a 19-mag, apparently stellar object. Spinrad and Smith[5] found that the optical object had a featureless spectrum at wavelengths > 4,400 Å and varied between $V = 17.5$ and 19.5 during 1972–74. They reported that the object was red ($B\text{–}V \simeq 1.3$) and had an apparent faint wisp of nebulosity extending 3″ S from the stellar source. Spinrad and Smith also cited radio observations that show a spectrum rising with increasing frequency and indicate variability at 6 cm; they suggested that AO 0235+164 is a BL Lac-type object with an unusually red colour.

The outburst of AO 0235+164

We have studied the recent outburst of this source in which it reached a magnitude of $V = 14.3$. Its spectrum has a strong and rich absorption-line system at $z = 0.524$, and probably a second system at $z = 0.852$. If these redshifts are of cosmological origin, AO 0235+164 reached a peak luminosity $\geqslant 3\times10^{14} L_{\odot}$, comparable with the outputs of the most luminous QSOs. Most of this energy fell in the infrared. AO 0235+164 is one of the most rapid variables and has one of the largest amplitudes and linear polarisation in the optical region found for any QSO-like object. Extensive observations show that the shape of the infrared spectrum fluctuated during the outburst. Our radio observations supplement those reported in papers by MacLeod *et al.*[27] and Ledden *et al.*[6] which provide a thorough record of the outburst in this spectral region.

On October 3, 1975, UT, AO 0235+164 was 2 mag brighter than its brightest reported by Spinrad and Smith. On the following night, it had brightened by a further 0.18 mag. Further photoelectric photometry, obtained occasionally during the outburst, was supplemented by photographic observations of the *B* magnitude. All of these measurements are summarised in Table 1 where they have been converted to flux densities using the calibration of Johnson[7]. The linear polarisation of AO 0235+164, measured with an unfiltered S-11 photocathode at the Kitt Peak National Observatory (KPNO) 4-m telescope, was $24.6\pm0.5\%$ at a position angle of 154.2° on October 4, 1975, UT, and only $6.1\pm1.2\%$ at a position angle of 126.4° on January 4, 1976, UT.

Measurements

The large range and rapidity of the optical variations and the high and varying polarisation are characteristic of BL Lac-type objects and confirm the classification by Spinrad and Smith. It is noteworthy that the $B\text{–}V$ colour (0.98 mag) was about the same as that found by Spinrad and Smith before the source had brightened by more than a factor of 10. The *UBV* colours of AO 0235+164 are similar to those of weak-lined red degenerate stars and are slightly redder than those of weak-lined subdwarfs, emphasising the importance of precise optical and radio positions for identifying objects of this type.

Infrared measurements, also summarised in Table 1, were begun on October 7, 1975, UT. It was possible to observe the source approximately every two weeks during the outburst because of a fortuitous arrangement of telescope schedules. Near maximum, AO 0235+164 was sufficiently bright that complete infrared spectra extending from 1–21 μm could be obtained. The star α Ari was used as a flux standard and the photometry was reduced according to the calibration described by F. J. Low[28]. Where appropriate, the measurements

The photographic observations on the KPNO 0.3-m and 0.4-m telescopes were made by C. T. Mahaffey using Kodak IIa-o emulsion and a Schott GG-385 filter. The photoelectric magnitudes of the comparison stars that were used to calibrate these plates (together with their coordinates relative to AO 0235+164) are:
(A) $V = 15.00$; $B-V = 1.21$ (13″ E; 21″ N).
(B) $V = 13.04$; $B-V = 0.58$ (32″ W; 32″ S).
(C) $V = 16.77$; $B-V = 1.49$ (7″ W; 78″ N).

have been corrected for the effects of the bandpass filter on the apparent fluxes[8].

Discussion of photometry

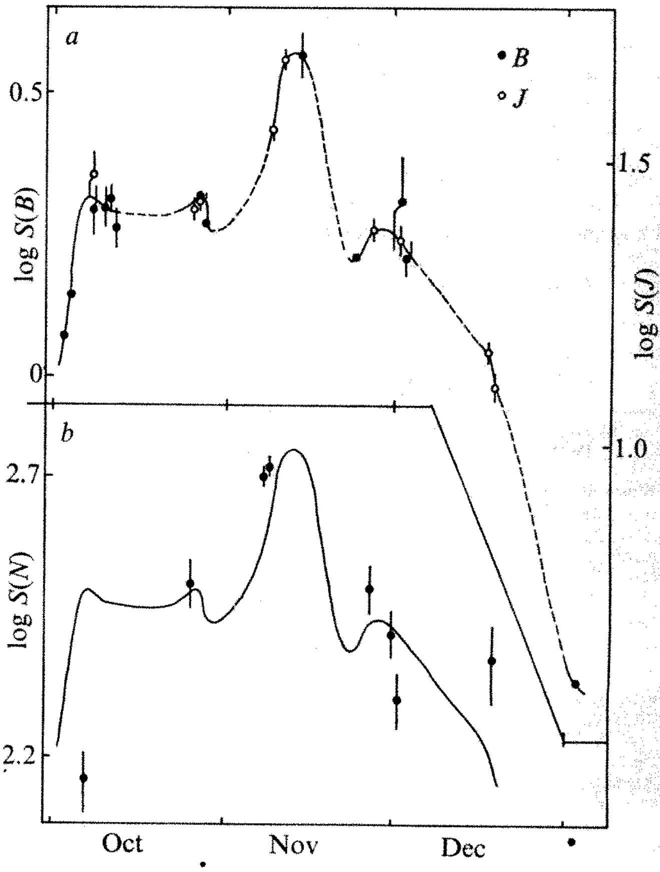
The infrared and visual light curves of AO 0235+164 are illustrated in Fig. 1. The behaviour of the source was roughly similar to that in a previous outburst during 1939–40, seen on plates in the collection of Harvard College Observatory[9]. The light curve is also similar to those of other BL Lac-type objects during violent outbursts, although AO 0235+164 is one of the most rapidly variable of this class.

From Fig. 1*a* it can be seen that the variations in the blue and near infrared are the same within the errors. The 10-µm observations, shown in Fig. 1*b*, give about the same amplitude as the visual curve, but appear to show different short time scale behaviour. The $U-B$ colour also varied slightly during the outburst. The radio flux reached a maximum at about the same time as in the optical and infrared, but the radio amplitude was considerably smaller[6]. From a comparison with the radio variations, because the source was relatively faint during our first observations, and because of the steep rise in the first part of the light curve, we believe that our first measurements were made during the initial phase of the outburst.

Variability of up to 30% on time scales of 1 or 2 d was seen both in the visible and infrared. Although we did not obtain sufficient simultaneous photometry in these two wavelength regions to prove that these fluctuations always occur simultaneously, that conclusion is indicated, since first, the infrared increase between November 9 and 11 was accompanied by an easily noticeable brightening as viewed through the telescope, and second, the spectral shape in each region implies that any variations should be simultaneous. Rapid variations of such large amplitude were not seen in the radio flux[6].

The photometric spectrum of AO 0235+164 on six occasions during the outburst is shown in Fig. 2. Where simultaneous measurements at all wavelengths were not available, the necessary extrapolations were based on Fig. 1*a*. The average correction for galactic extinction at the latitude of AO 0235+164 (−39°) is only 0.01 mag in $U-B$ and 0.02 mag in $B-V$

Fig. 1 Light curves of AO 0235+164 with flux densities in mJy. The upper panel (*a*) is for *B* (0.44 µm) and *J*(1.25 µm) except that the last point of *J* was obtained from a measurement at 2.2 µm and the mean [1.25 µm–2.2 µm] colour. The lower panel (*b*) is for *N*(10 µm); some narrow-band measurements near this wavelength have been combined to increase the statistical weight. The curve is the same as that used in (*a*).



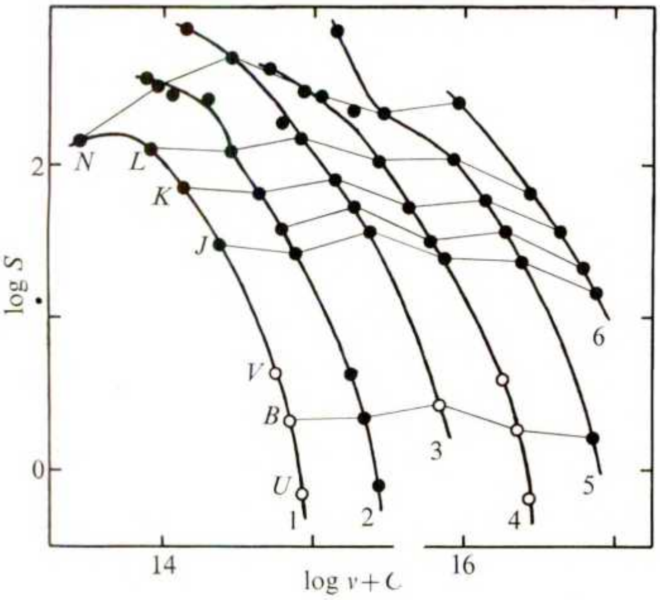


Fig. 2 Photometric spectra of AO 0235+164 with flux densities in mJy. Thick lines join measurements taken at the same time while thin lines connect measurements at the same frequency. For clarity, successive epochs are displaced sideways. The 1975 UT dates and values of the constant C are: curve 1—Oct. 7–8, $C = 0$; curve 2—Oct. 26–27, $C = 0.5$; curve 3—Nov. 8–9, $C = 1.0$; curve 4—Nov. 27, $C = 1.5$; curve 5—Dec. 1–2, $C = 2.0$; curve 6—Dec. 18–19, $C = 2.5$. ○, points that were extrapolated according to Fig. 1*a* by > 24 h.

(ref. 10), and there is no indication of strong localised extinction near the source. The (10.6–0.44 µm) and (0.55–0.36 µm) spectral indices varied over the ranges -1.49 ± 0.14 and -4.14 ± 0.12, respectively. Although the spectra of most BL Lac-type objects are slightly curved between 0.4 and 10 µm (ref. 11), that of AO 0235+164 has substantially greater curvature and is steeper than is typical.

The spectra in Fig. 2 show the effects of the different short term variability beyond 4 µm. Although these effects are apparent throughout the outburst, they are particularly striking at the beginning when the spectrum appears to turn over near 10 µm. Another explanation — that the source brightened by a factor $\gtrsim 2$ between October 7 (when the 10 µm data were obtained) and October 8 (when the other measurements were made)—seems unlikely because there was no noticeable brightening observed visually between these two dates, and fluctuations of the required amplitude and speed were not seen at any other time. Instead, it seems that the flux rose more slowly at 10 µm than at shorter wavelengths.

The 90 and 140 GHz measurements of AO 0235+164, summarised in Table 2, together with other mm-wave flux densities, indicate a maximum which occurred at about the same time as in the optical and infrared, but they show a slower decay. The radio outburst is discussed in detail in refs 6 and 27.

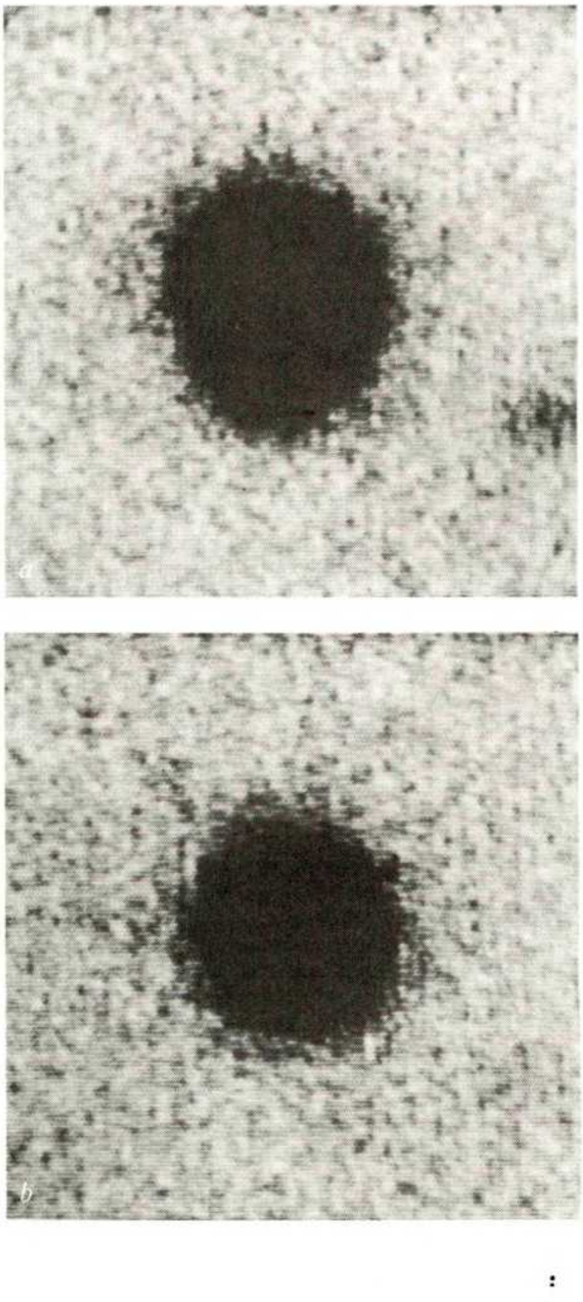
Photographic results

A deep plate in the yellow–red (Eastman Kodak 127-04 emulsion and Schott GG-495 filter) was taken at the prime focus of the KPNO 4-m telescope on January 4, 1976, UT, when the object was at $B \simeq 18.0$. The image of AO 0235+164 on this plate, and that of a star of comparable brightness (6″W and 187″N), were scanned on the PDS microphotometer at KPNO using a square raster scan of side 13″ and a scanning aperture of 0.15″. These data were displayed on the COMTAL television monitor of the KPNO Interactive Picture Analysis system[12]. Identical optimum adjustments were made to show the faint extensions of the images; photographs of this display

Fig. 3 Photographs of a television reconstruction of the images of *a*, AO 0235+164 and *b*, a nearby star to show the southerly extension of the former. North is to the top and E to the left, and each square has a side of 13″.



are shown in Fig. 3. The southerly extension of the image of AO 0235+164 found by Spinrad and Smith is confirmed, but its maximum extent (~ 3″) is no greater than that reported by them, even though the KPNO plate is deeper. A nebula or galaxy associated with the source is an exciting possibility, but our observation is also consistent with the existence of a faint, superposed star.

Absorption-line spectrum

A spectrogram of AO 0235+164, obtained under poor conditions on November 25 with the Steward Observatory 2.25-m telescope, showed an absorption feature which was identified as the Mg II doublet. Spectrograms were independently obtained between December 3 and 8 (UT) using a two-stage image-tube spectrograph on the 2.7-m telescope of McDonald Observatory. The reciprocal dispersion was 110 Å mm^{-1} and baked IIIa-J emulsion was used, giving a resolution of ~ 3 Å over the spectral range 3,500–5,500 Å. As an illustration, a density tracing of one of these spectrograms is shown in Fig. 4. Some of the features are clearer on other spectrograms; in particular, the lines near 3,600 Å are seen most clearly on a spectrogram optimised for that region. The existence of some of the weak lines is supported by their detection on a number of spectrograms.

The principal feature in the spectrum is a well resolved pair of deep, sharp absorption lines which we identify as the Mg II ($\lambda = 2,795.5$ and 2,802.7 Å) doublet at a redshift $z = 0.5242 \pm 0.0002$; the width of these lines is < 2 Å in the rest frame. There are many other absorption lines, identified as Mg I, Fe II, and Mn II; these are listed in Table 3, together with the number of spectrograms on which each line was measured.

All the lines listed as strong in Table 3 were also seen in PHL938 (ref. 13) and in PKS1331+170 (ref. 14) and are those predicted by Bahcall[15] to be the most easily detectable in QSOs within the range of rest-wavelengths covered by our spectrograms. The Mg I and Mn II lines have not been found previously in QSO spectra, but their identification is supported by a comparison with the ultraviolet spectrum of ζ Oph (ref. 16, and E. M. Burbidge, *et al.*, ref. 29). In fact, all the lines which occur in the appropriate wavelength region for the $z = 0.524$ system and which have equivalent widths > 30 mÅ in the spectrum of this star are also seen in the spectrum of AO 0235+164. The rich absorption-line spectrum at $z = 0.524$ removes any doubt about the correctness of the identification of the Mg II doublet in this object and, by analogy, in PKS0735+178.

On three of the spectrograms there is a pair of absorption lines near 5,176 and 5,190 Å which cannot be readily identified if their redshift is 0.5242. Figure 5*a* shows the averaged density scan of these spectrograms; we suggest that the lines are the Mg II doublet at a redshift of 0.8516 ± 0.0007. Since these Mg II lines are only about one-quarter of their strength in the $z = 0.524$ system, even the strongest Fe II lines should be only barely detectable in the 0.852 system. A weak line measured at $4,412.2 \pm 0.7$ Å on three spectrograms corresponds to Fe II ($\lambda = 2,382$ Å) and the composite tracing shown in Fig. 5*b* lends further support to the reality of this line. The dip near 4,811 Å in Fig. 4 corresponds to the expected position of Fe II ($\lambda = 2,599$ Å) in the $z = 0.852$ system; it was not seen on the other three spectrograms, but they were less densely exposed in this wavelength region. The Fe II ($\lambda = 2,343$ Å) line would occur only 8 Å to the blue of the Mg I line (see Fig. 5*b*) and would therefore be difficult to detect. Since the redshifts of emission-line systems in QSOs are usually at least as large as the largest absorption-line redshift, the continuum of AO 0235+164 is probably at $z \geqslant 0.852$. Our spectroscopic results are in good agreement with those of Burbidge *et al.*[29], although our measurements extend further into the ultraviolet.

Table 3 Absorption lines in AO 0235+164

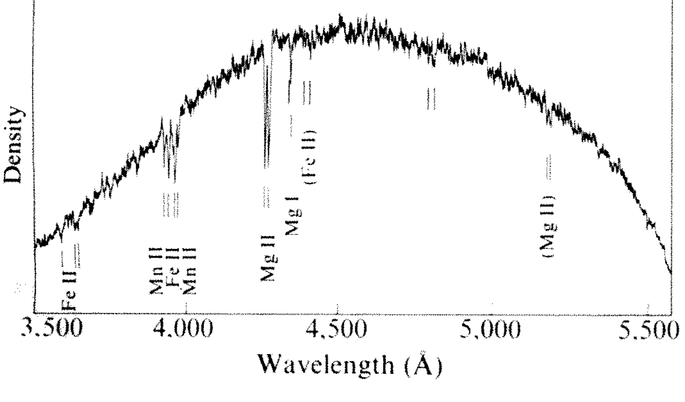
*S, M, W = strong, medium, weak absorption relative to the continuum.

Fig. 4 A density tracing of a spectrogram of AO 0235+164. Symbols without parentheses denote line identifications in the $z = 0.524$ redshift system, while symbols within parentheses indicate lines in the $z = 0.851$ system. The vertical lines without symbols show the expected positions that weaker members of the $z = 0.524$ system would have with a redshift of $z = 0.851$.



Emission lines

AO 0235+164 showed no emission lines on any of our spectrograms, including one exposed between 3,700 and 7,000 Å at a reciprocal dispersion of 240 Å mm^{-1}, which should have been particularly sensitive to broad lines. The presence of strong absorption lines without emission lines is very uncommon among known QSOs, a situation that may be partly a result of selection effects. Schmidt[17] noted the rare case of 4C 28.25, a QSO with an absorption-line system consisting of the Mg II doublet and the Fe II lines $\lambda = 2,382$ Å, $\lambda = 2,586$ Å, and $\lambda = 2,599$ Å with a redshift of $z = 0.8907$. 4C 28.25 also has weak emission features identified with C III and Mg II with a redshift of $z = 0.899$. 4C 28.25 is, therefore, intermediate between an emission-line QSO and objects like AO 0235+164. We also note that incipient emission with a redshift close to that of the absorption spectrum could distort the profiles of the absorption lines in AO 0235+164 and invalidate estimates of multiplet ratios.

Discussion

The relative line strengths in the $z = 0.524$ system may be difficult to reconcile with strictly solar abundance ratios in the gas and simple density and velocity distributions. The arguments in this paragraph are supported by the detection of structure in the 21-cm absorption line at $z = 0.52385$[30]. For example, explaining the relative strengths of the Mg II and Fe II lines by having them form lower on the curve of growth than in ζ Oph (E. M. Burbidge, *et al.*, ref. 29)—assuming a relatively

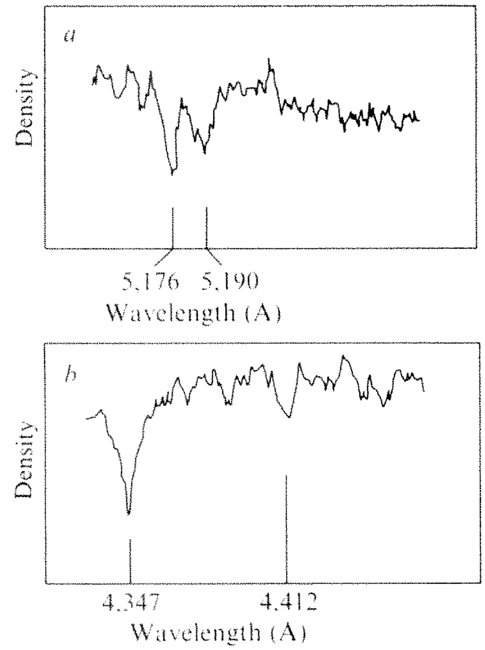


Fig. 5 Composite density tracings of the spectrograms to show the features in the $z = 0.852$ redshift system: *a*, the region of the Mg II doublet (5,176 and 5,190 Å) from three spectrograms and *b*, the region of the Fe II at $\lambda = 2{,}382$Å (4,412 Å) from four spectrograms.

low column density and high velocity dispersion—would require an overabundance of Mn and would be hard to reconcile with the relative strengths of the Fe II lines at 3,619, 3,631, 3,941, and 3,963 Å. If the relative strengths of the Mg II and Fe II lines are a result of a very high column density and small velocity dispersion[18], the Fe II lines should be more strongly saturated than indicated by the equivalent widths given by Burbidge *et al.*

High column densities might also result in heavy extinction, particularly if the absorption lines arise in an intervening galaxy with an absorption line–extinction ratio similar to that found in interstellar clouds in our own Galaxy. Extinction could contribute to the large curvature of the spectrum of AO 0235+164. The *UBV* colours of AO 0235+164 would be consistent with those of a typical BL Lacertae object with an additional reddening of ~ 0.5 mag in its $B-V$ colour. Mg II column densities of as much as 10^{+17} cm^{-2} (a possibility suggested by Wolfe and Burbidge[18] for PKS0735+178 for which the doublet is slightly weaker) lead, however, to enormous values of the reddening, if the extinction process is similar to that which applies to the interstellar material in our own Galaxy. For example, ζ Oph, with a Mg II column density of only 10^{15} cm^{-2} (ref. 15) has $E_{B-V} \simeq 0.3$. Also, PKS0735+178 does not appear to be significantly reddened. An intrinsic ultraviolet cutoff in the continuum provides an attractive explanation for the lack of emission lines in BL Lacertae-type sources. AO 0235+164 may be the first such object found at sufficiently high redshift that a cutoff is detectable through *UBV* photometry.

Most of the detected energy from AO 0235+164 was in the infrared and its peak luminosity was $\geqslant 3\times10^{14}L_{\odot}$, if it is at the Euclidean distance implied by the redshift of $z \geqslant 0.852$ ($v/c = 0.55$) and a Hubble constant of 55 km s^{-1} Mpc^{-1}. The total flux density change is 2 orders of magnitude, but its outbursts seem to be relatively infrequent and of sufficiently short duration that the total energy emitted at the lower level of activity is comparable with that released during outbursts. The peak luminosity of AO 0235+164 was $\sim 10^5$ times greater than the luminosity measured for the nuclear source in B2 1101+38[20]. This source has similar properties in other respects: a radio spectrum that is flat or rises with increasing frequency, past large amplitude variability, large and variable intrinsic polarisation, and an absence of emission lines[20,21]. Thus, a single phenomenon seems to operate at power levels ranging from those typical of moderately active galactic nuclei up to those associated with the most luminous QSOs.

Constraints on models

It is generally believed that the radio emission from sources of this type is some form of synchrotron radiation[21]. AO 0235+164 is an outstanding example where the cosmological interpretation of the redshift and the time scale of the variability are very difficult to reconcile with this hypothesis without invoking highly relativistic motion or a special geometry[22].

Attempts to explain the optical and infrared emission as synchrotron radiation encounter even greater difficulties. Except for B2 1101+38 (ref. 23), these sources have not been detected in the X-ray region[24,25] (the pre-outburst Uhuru upper limit for AO 0235+164 is 1.7 × 10^{-10} erg cm^{-2} s^{-1}). To reconcile the lack of Compton-scattered X-ray fluxes with the high surface brightness implied by the rapid fluctuations, very large magnetic fields and very special geometries are required[26,2]. Further X-ray observations during the outbursts of these sources are urgently needed.

Any plausible model for optical synchrotron emission would probably require a sufficiently large magnetic field so that synchrotron self-absorption would occur in the infrared[11]. The behaviour of the spectrum of AO 0235+164 beyond 4 μm and the differences between the radio and optical–infrared light curves could be taken as evidence for self-absorption.

It has not yet been demonstrated, however, that self-consistent models can be constructed along these lines, and our observations of AO 0235+164 strengthen the difficult constraints on solutions to the problem. It is possible that some other, not yet understood emission mechanism is operating, or that these sources are not at the cosmological distances indicated by their redshifts.

We wish to thank Dr H. Spinrad and Dr E. M. Burbidge for sending us their papers in advance of publication. We are grateful to Drs M. Schmidt, P. A. Strittmatter, and R. E. Williams for discussions. We would also like to thank Dr M. J. Belton for making the 0.3-m Schmidt available to us at short notice, Dr D. Wells for technical assistance with the Kitt Peak Interactive Picture Analysis System, and Dr G. F. Benedict for producing the density scans of our spectrograms.

The work of G.H.R. and also that of B.J.W. and D.W. was supported by grants from the US NSF. Kitt Peak National Observatory is operated by the Association of Universities for Research in Astronomy, Inc., under contract with the NSF.

Messenger RNA for the coat protein of tobacco mosaic virus

Tony R. Hunter* & Tim Hunt

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2HQ, UK

TMV RNA is not an efficient template for translation of the viral coat protein, in spite of containing nucleotide sequences coding for the protein. Efficient translation requires the prior synthesis within infected cells of a smaller RNA carrying only a portion of the information encoded in the whole genome.

TOBACCO mosaic virus (TMV) consists of an infectious single-stranded RNA molecule 6,400 nucleotides long, encapsidated by 2,100 identical coat protein molecules each with a molecular weight of 17,500 (ref. 1). This packaged RNA (virion RNA) is the sense strand for the translation of coat protein, as was first shown by patterns of mutagenesis[2,3] and more recently by direct nucleotide sequence analysis[4]. The coat protein gene must consist of at least 480 residues of virion RNA. Thus less than 10% of the RNA is accounted for by the coat cistron.

As would be expected, the RNA acts as a good message in cell-free translation systems from bacteria[5], plants[6] and animals[7], but analysis of the products of such incubations has repeatedly shown that coat protein is not the major product, and careful studies with the *E. coli* cell-free system eventually proved that ribosomes never passed over the coat protein cistron in the correct phase[8,9]. This might be due to general incompatibility between eukaryotic and prokaryotic mRNA and ribosomes, but studies of the translation of TMV RNA in various eukaryotic protein synthesising systems have given similarly negative results, thus suggesting that translation of coat protein is not straightforward, and raising the problem of how the coding sequences known to be present on the RNA actually are expressed. In the wheat germ cell-free system, for example, the major products are much larger than the coat protein and also very heterogeneous. Nevertheless Efron and Marcus[6] detected labelled coat protein peptides in products which migrated with authentic coat protein on gel filtration, although they represented only a very minor fraction of the total incorporation. In contrast, when Roberts *et al.*[10] used RNA from the TMV mutant Ni 568, they failed to detect significant levels of product with the mobility of coat protein on acrylamide gels. They did, however, find a coat protein peptide among the products of their incubation, at very low yield, and it was suggested[11] that the coat protein is made as part of a large precursor which is processed by proteolysis to yield mature coat, as in the case of picornaviruses. This idea is inconsistent with the data of Efron and Marcus, who failed to find any coat protein peptides in material larger than coat protein.

We have used two other eukaryotic systems to translate TMV RNA, and have found that it directs the synthesis of discrete polypeptides, which simplifies interpretation (ref. 7 and our unpublished results). In *Xenopus laevis* oocytes[7] and in reticulocyte lysates, the products directed by TMV RNA are two large polypeptides with molecular weights of 140,000 and 165,000; the first corresponds to the largest product of the wheat germ system. We have never detected the synthesis of coat protein. The 140,000 polypeptide does not contain coat protein sequences detectable by tryptic peptide mapping[7] and, given the results reported here, it does not seem likely that the coat is contained within the 165,000 molecular weight polypeptide either. We believe that these proteins are authentic translation products of cistrons in TMV RNA other than the coat cistron, for similar sized proteins are made in TMV-infected leaves and protoplasts[12,13]. In synchronously infected protoplasts, these two proteins are readily detectable about 5 h after infection and there is a further lag of about 4 h before coat protein synthesis begins. Late after infection the synthesis of the two large proteins declines, but coat protein synthesis continues at very high levels. It is difficult to interpret these findings, particularly the latter observation, in terms of a precursor–product relationship between the largest proteins and the coat protein.

It thus seems that there is some temporal and quantitative control of gene expression in TMV, as has been found in essentially all RNA viruses (with the exception perhaps of the picornaviruses), and that most of the extra RNA in TMV which does not code for coat protein codes for the proteins of molecular weight 140,000 and 165,000. If this is correct, and cell-free systems and *Xenopus* oocytes make essentially only 'early' TMV proteins, then how is the coat protein made? We extracted TMV-infected tobacco leaves to see if we could find and characterise the mRNA for

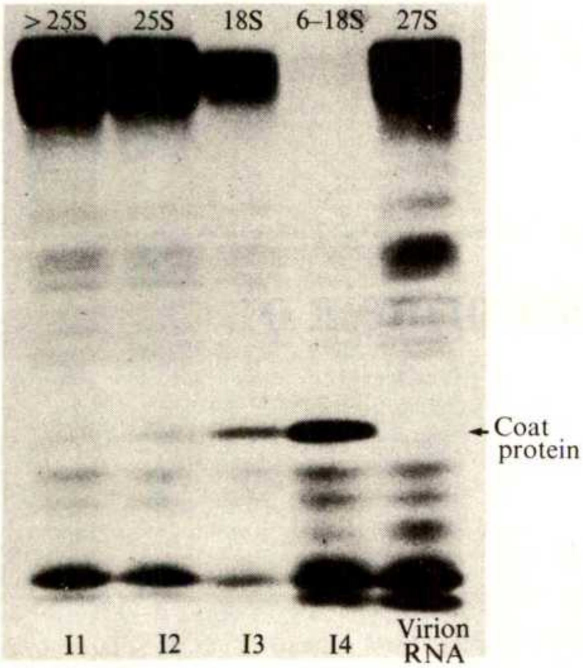

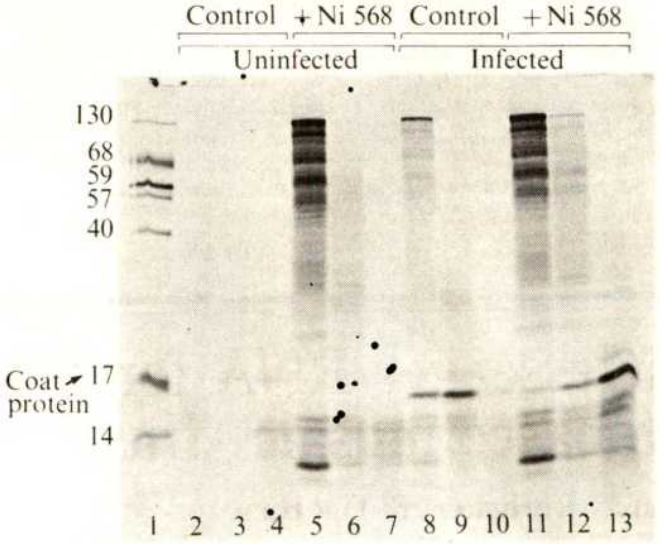

Fig. 1 *a*, Translation of RNA of different size classes from tobacco leaves infected with TMV. Tobacco leaves, infected 7 d previously with TMV vulgare, were washed in water, ground in liquid nitrogen and extracted in an equal mixture of water-saturated phenol and buffer A (10 mM EDTA, 1% SDS, 50 mM Tris–Cl, *p*H 8.8) at 65 °C. The aqueous phase was extracted four more times with phenol, made 0.1 M in NaCl and precipitated with 2 volumes of ethanol. The precipitate was taken up in 1 mM EDTA, 0.5% SDS; warmed for 1 min at 65 °C, and spun at 10,000*g* for 30 min at 4 °C to remove undissolved material. The supernatant was layered over 15–40% (w/v) sucrose gradients in 0.1% SDS, 1 mM EDTA, 20 mM Na acetate, *p*H 5.0, and spun in a Beckman SW 27 rotor for 18 h at 27,000 r.p.m. at 15 °C. The gradients were pumped through a recording spectrophotometer and fractions were pooled as follows: I1 > 25S; I2 ~ 25S; I3 ~ 18S; I4 18S-6S. The RNA fractions were reprecipitated from 0.2 M Na acetate with 3 volumes of ethanol. The precipitates were taken up in water, and stored in liquid nitrogen, except for fraction I4 which was diluted in 1 mM EDTA, 1% SDS, 2 M LiCl and precipitated overnight at 4 °C (ref. 45). The precipitate was recovered by centrifugation at 10,000*g* for 10 min, and taken up in water before ethanol precipitation as above. Each fraction, and RNA extracted from TMV virions, was tested for template activity in a cell-free wheat germ system prepared and incubated as described by Roberts and Paterson[16], except that the ionic conditions in the incubation were: 80 mM KCl, 1.5 mM $MgCl_2$, 0.8 mM spermidine, 20 mM HEPES, *p*H 7.2. The labelled amino acid was L-^{3}H-leucine (20 Ci mmol^{-1}, 10 μM). Reactions were stopped by incubation with pancreatic RNase (100 μg ml^{-1}) for 15 min at 30 °C. Four volumes of SDS gel sample buffer were added[17] and the samples were analysed on 20% SDS-acrylamide gels. After fixing and staining, the gels were impregnated with PPO according to Bonner and Laskey[18] and exposed to Kodak RP Royal X-ray film at −70 °C. The fluorogram shows the products directed by fractions I1–I4, and virion RNA. All RNAs were present at 200 μg ml^{-1} in the incubations. A control without added messenger showed no detectable blackening of the film. *b*, Control for degradation of RNA during extraction. RNA was prepared and fractionated from either uninfected leaves (tracks 2–7) or TMV vulgare-infected leaves (tracks 8–13) as described in (*a*), except that 1 mg of purified Ni 568 virus was added per g wet weight of ground leaves to half of each leaf sample just before phenol extraction (tracks 5–7 and 11–13). The RNA was fractionated by size and the three larger size classes were tested for their template activity as described above, except that products were analysed on a 15% SDS–polyacrylamide gel. The markers in track 1 are β galactosidase, bovine serum albumin, pyruvate kinase, glucose-6-phosphatase, creatine kinase, TMV coat protein and lysozyme, all labelled with ^{14}C-iodoacetic acid.

coat protein, since large amounts of coat protein are made in infected cells, and thus some functional messenger of high efficiency clearly exists. This could in theory be the virion RNA complexed with some control protein, but there were indications from earlier work that the actual messenger might be a smaller RNA[14,15]. This could explain the marked discrepancy between the apparently faithful synthesis of the 140,000 and 165,000 molecular weight polypeptides in *in vitro* systems, and the total lack of coat protein synthesis in the same systems when programmed with virion RNA, implying that the coat cistron in virion RNA is repressed.

Preliminary experiments

RNA was extracted from tobacco leaves which had been systematically infected with TMV 7 d previously. They were frozen and pulverised in liquid nitrogen before extraction in hot phenol–sodium dodecyl sulphate (SDS). After several phenol extractions, RNA was precipitated with ethanol, and after resuspension in aqueous buffer, fractionated on sucrose gradients. Fractions from the gradients were pooled according to their sedimentation rate and recovered by ethanol precipitation. The slowest sedimenting fraction was very heavily contaminated with carbohydrate, and was further purified by precipitation with 2M LiCl at 2 °C overnight. Each fraction, as well as corresponding fractions from uninfected plants, was added to cell-free extracts of wheat germ, and incubated essentially according to Roberts and Paterson[16]. The incubations were analysed by SDS–polyacrylamide gel electrophoresis on slabs[17], followed by fluorography[18] to detect ^{3}H-labelled polypeptides. Figure 1*a* shows the result of one such experiment. A strongly radioactive band with the same electrophoretic mobility as coat protein was made only in incubations programmed with RNA from TMV-infected leaves, and not in incubations programmed with virion RNA. Furthermore, maximal synthesis occurred when the smallest RNA fractions were used, suggesting that the active template was an RNA molecule considerably smaller than intact TMV RNA.

An obvious objection to the straightforward interpretation that a small RNA molecule is the natural mRNA for TMV coat protein is that it might have arisen by degradation of virion RNA during extraction of the leaves. We sought to exclude this possibility by the experiment shown in Fig. 1*b*. The mutant TMV strain Ni 568 contains a single methionine residue in its coat protein[2], unlike the wild-type strain vulgare which contains no methionine. We therefore repeated the extraction of RNA from leaves infected with TMV vulgare, but added a large amount of purified TMV strain Ni 568 virus just before the phenol extraction. After extraction and fractionation of the RNA as before, the fractions were tested in the wheat germ system using either ^{35}S-methionine or ^{3}H-leucine as label in parallel incubations. The products were analysed on slab gels as before; the results of the incubations with ^{3}H-leucine as label are shown in Fig. 1*b*. No coat protein-like products were seen in RNA from uninfected plants, whether or not TMV Ni 568 had been added during extraction. In contrast, such a protein was synthesised when RNA from infected plants was used, but it was labelled only with leucine, and not with methionine. This shows that RNA from the added virions is not converted into a form capable of being translated into the putative coat protein by degradation or modification during extraction of the RNA from leaves. The experiment also shows that uninfected leaves do not contain detectable mRNA for this protein. It should be noted that since typical virion RNA-directed products are observed in the track corresponding to the uninfected plants to which Ni 568 RNA had been added, this RNA was extracted efficiently. Furthermore, the amount of products formed suggested that we had added about the same amount of virion RNA as was naturally present in the infected leaves (compare track 5 with track 8 in Fig. 1*b*). We are therefore confident that the RNA which promotes the synthesis of the putative coat protein is not an artefact of degradation on phenol extraction.

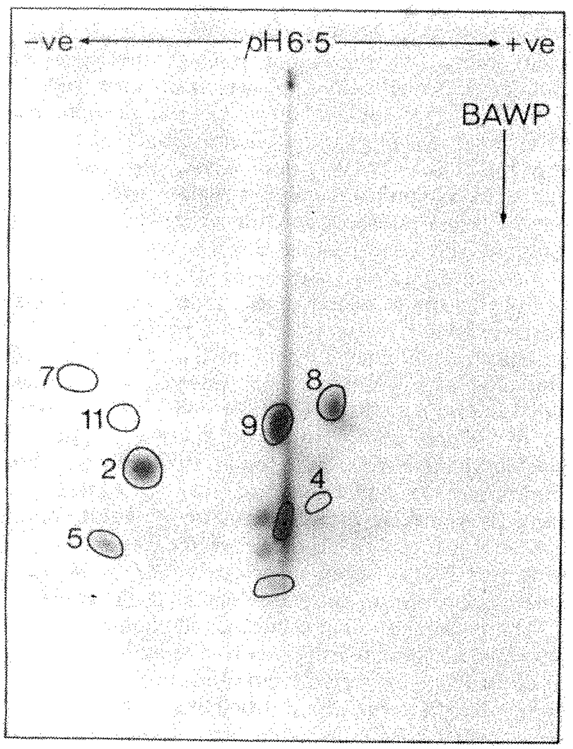

Fig. 2 Fingerprint of putative coat protein synthesised *in vitro*. Fraction I4 RNA from infected leaves was injected into 20 *Xenopus* oocytes, which was incubated in medium containing 20 μCi of L-^{14}C-valine (280 μCi μmol^{-1}) for 24 h. They were homogenised as described previously[7] with 100 μg of authentic TMV vulgare coat protein. The homogenate was centrifuged, and the supernatant fractionated by electrophoresis on an 18% SDS-polyacrylamide gel. The gel was stained with Coomassie blue, dried, and autoradiographed. The stained coat protein band, which was heavily labelled, was cut into small pieces. 2 ml of 10 mM Tris–Cl, *p*H 7.0, 0.1% 2-mercaptoethanol, 2% SDS were added, and the suspension was incubated for 10 min at 95 °C and for 18 h at 37 °C. The bits of paper and gel were filtered off, and the protein was recovered from the filtrate by precipitation with trichloroacetic acid (TCA). It was oxidised and digested with trypsin[7] and the soluble peptides were separated by electrophoresis at *p*H 6.5, 20 V cm^{-2} on a 20-cm^{2} Silica gel G thin layer (250 μm) (Anachem)[46], followed by chromatography in butanol–acetic acid–water–pyridine (30:6:24:20) at right angles to the first dimension. After autoradiography, the carrier TMV coat protein peptides were stained with fluorescamine[47]. The stained peptides (outlined) are numbered from the N-terminus; peptides 4, 7 and 11 do not contain valine.

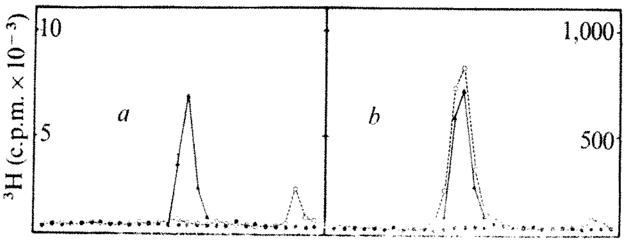

Fig. 3 Assembly of the *in vitro* product. Four cell-free incubations using the wheat germ system programmed with either fraction I4 RNA from TMV-infected leaves or 27S virion RNA, were labelled with ^{35}S-methionine or ^{3}H-leucine. After incubation for 1 h, the ^{3}Hl- and ^{35}S-labelled samples corresponding to each template were mixed together, and 1.8 mg of TMV coat protein was added to both mixtures. The two mixtures were dialysed against 10 mM Tris–Cl, *p*H 8.0, and passed over 0.5-ml columns of DE 52 cellulose equilibrated with the same buffer. After washing with buffer, the coat protein was eluted with 0.2 M KCl, 10 mM Tris–Cl, *p*H 8.0. This material was dialysed against 10 mM Na acetate, *p*H 5.0, to form the helix aggregate[31], which was collected by centrifugation at 100,000*g* for 1.5 h, suspended in Na phosphate buffer, *p*H 7.0, ionic strength 0.1, made 5 mg ml^{-1} in coat protein by a further addition of carrier, and dialysed overnight at 4 °C against the same buffer. The sample was then incubated at 20 °C for 18 h to form disks, at which time TMV RNA (1 mg ml^{-1}) was added, and incubation continued for 10 min at 20 °C. Uncoated RNA was digested with T1 RNase (20 μg ml^{-1}) for 1 h at 20 °C, and the partially reassembled virions were purified by two cycles of preparative CsCl density gradient centrifugation, using added ^{32}P-labelled TMV as marker, in the Beckman SW 50 rotor (CsCl, 1.33 g ml^{-1}, 32 h at 35,000 r.p.m.). The fractions containing marker virus were analysed finally in 8-ml CsCl gradients in the 50 angle head rotor, spun at 40,000 r.p.m. for 24 h. *a*, Result of attempted assembly using the translation product specified by 27S virion RNA; *b*, that using incubations programmed with fraction I4 RNA. Overall recovery of radioactivity from the ^{3}H-labelled incubation programmed with coat mRNA in the peak of CsCl-banded reassembled virus was about 10% while essentially no radioactivity from any other incubation survived to the final analysis. ▲, ^{32}P radioactivity; ○, ^{3}H radioactivity; ●, ^{35}S radioactivity.

Characterisation of the product

The new band programmed by RNA from infected leaves has the same mobility on SDS gels as authentic TMV coat protein, and it lacks methionine. We also found that histidine failed to label the gel band, which would be expected of coat protein, which lacks both methionine and histidine.

When the RNA from TMV-infected leaves was injected into *Xenopus* oocytes, it directed synthesis of a similar band. The yields were higher, and the background lower than in the wheat germ system, and we therefore used oocyte synthesised material to make a tryptic peptide map (Fig. 2). There is excellent correspondence between the *in vitro* synthesised peptides, labelled with ^{14}C-valine, and the fluorescamine-stained carrier peptides, except in the case of coat protein peptides that lack valine. We conclude that this material is chemically indistinguishable from TMV coat protein.

We next asked whether the putative coat protein could be assembled into virus particles *in vitro;* that is whether it resembled coat protein by functional as well as chemical criteria. We therefore partially purified the *in vitro* synthesised coat protein by chromatography on DEAE-cellulose, a procedure which removes basic proteins which may bind nonspecifically to viral RNA during the assembly process. After elution from the column, the protein was concentrated by precipitation at *p*H 5, dissolved in buffer (*p*H 7) and mixed with TMV RNA. After digestion with T1 RNase to remove uncoated RNA tails, the reconstitution mixtures were analysed by CsCl gradient centrifugation with the result shown in Fig. 3. Of four reaction mixtures, using the products labelled with either ^{3}H-leucine or ^{35}S-methionine, programmed by either coat protein mRNA or virion RNA, only the one with coat protein mRNA and ^{3}H-leucine as label gave radioactively labelled nucleoprotein of the same buoyant density as added $^{32}PO_4$-labelled TMV. Furthermore, the labelled protein extracted from this reconstituted nucleoprotein migrated with authentic TMV coat protein on polyacrylamide gels, and no other labelled bands could be detected on the fluorogram. This was in marked contrast to the starting material, which contained many other labelled polypeptides besides coat protein. We conclude from these experiments that a small RNA species present in TMV-infected cells, and not an artefact of extraction, programmes the *in vitro* synthesis of a protein which is chemically and functionally indistinguishable from TMV coat protein.

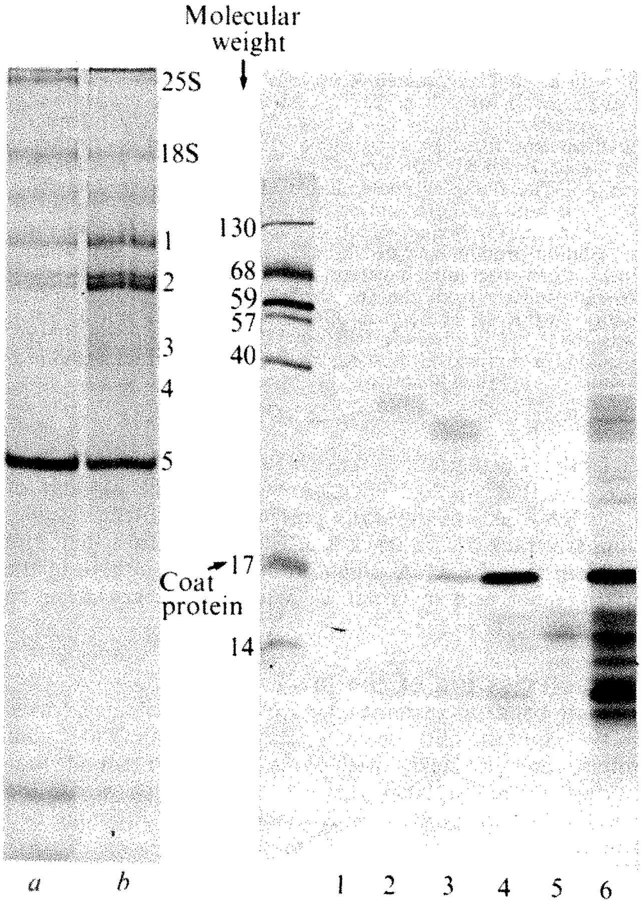

Fig. 4 Fractionation of the coat protein mRNA by gel electrophoresis. On the left are shown two tracks from a 2.8% Agarose/acrylamide gel stained with Stainsall (Eastman Chemicals). *a*, 6–18S RNA from uninfected tobacco leaves; *b*, 6–18S RNA from TMV-infected leaves. The indicated bands from parallel unstained tracks were cut out and the RNA was extracted from them by homogenisation in an equal mixture of phenol and buffer containing 0.1 M NaCl, 10 mM Tris–Cl, *p*H 7.5, 1 mM EDTA, 1% SDS, with 50 μg of carrier yeast tRNA. After extraction for 6 h at 0 °C, the tubes were centrifuged and RNA precipitated from the supernatants with 2.5 volumes of ethanol. The precipitates were washed with ethanol before being taken up in water and tested for template activity in the wheat germ system as described in Fig. 1. The autoradiograph on the right shows the analysis on a 20% acrylamide gel of the products specified by fraction I4 RNA (track 6) and RNA from the indicated gel bands (tracks 1–5). The positions of molecular weight markers are indicated in the left margin of the gel.

Characterisation of the RNA

Up to this point, the fractionation of RNA by sucrose density gradients provided only partially pure coat protein mRNA, but one would expect the coat mRNA activity to reside in a discrete RNA species if it were of genuine biological significance. We therefore took our most active fraction of gradient purified RNA and fractionated it further on an Agarose/acrylamide gel[19]. Figure 4 shows a gel stained with Stainsall[20]; adjacent tracks contain RNA from TMV-infected and uninfected tobacco leaves. We found a reproducible minor stained band in infected leaves which was absent in control leaves. To see if it was coat protein mRNA, a gel with duplicate tracks was run, and one track was stained while the other was cut into bands and the RNA was extracted. We found that RNA from the new gel band was an excellent mRNA for coat protein (Fig. 4). Some of the slower migrating bands also programmed the synthesis of small amounts of coat protein, besides making larger proteins as one would expect. We do not know whether this represents a certain amount of trailing on the gel or of aggregation (since these were not denaturing gels), or whether there may perhaps be larger RNA molecules with coat protein mRNA activity. We estimate that the molecular weight of the major mRNA species is about 2.5×10^5, or 750 nucleotides, of which at least 480 would be required to code for coat protein. Coat protein mRNA failed to bind to oligo(dT)–cellulose (data not shown), showing that, like TMV virion RNA, the coat protein message lacks a significant poly(A) region.

From the classical work mentioned in the introduction, we expected the coat protein mRNA to have the same polarity as virion RNA, and since large end products of RNase T1 digestion which come from the coat cistron have already been characterised[4,21], we sought these characteristic markers in coat protein mRNA. Tobacco plants were infected with TMV and labelled by growing them in medium containing $^{32}PO_4$. Coat protein mRNA was extracted as before, and purified on sucrose gradients and Agarose/acrylamide gels. We found the expected marker oligonucleotides in fingerprints of the T1 RNase digests (Fig. 5*b*), thus proving directly that the gel band contained nucleotide sequences from the expected region of virion RNA, so that it is a fragment of the viral (+) strand, and does not come from an unrelated RNA, such as a satellite virus. There was another unexpected bonus from this analysis, in that the fingerprint bore a striking resemblance to that of an RNA extracted from a nucleoprotein fragment of defined length (containing 1,000 nucleotides) which is generated when TMV particles are degraded in mildly alkaline conditions[22,23]. The RNA from this 'alkali stable fragment' has independently been shown to contain the 3′ terminal T1 oligonucleotide of TMV in molar yield[24], and can be charged with histidine by yeast activating enzymes, as is the case for intact TMV RNA[25]. Analysis of the T1 RNase fingerprint of this fragment showed that it also contained the marker oligonucleotides found in the coat protein mRNA (Fig. 5*a*), showing that the part of the coat cistron from which they originate must be within 1,000 nucleotides of the 3′ end of TMV RNA. Furthermore, the purified coat protein mRNA was found to contain a T1 oligonucleotide which gave rise to the pancreatic RNase products (AAU, C_5,G). This is probably identical with the oligonucleotide AAUCCCCCG which occurs about 20 nucleotides from the 3′ end of intact virion RNA[26]. This suggests that the coat protein mRNA probably corresponds to the 3′ terminal 750 nucleotides of virion RNA.

This assignment of the location of the coat protein cistron is at the opposite end of the RNA to that found by Kado

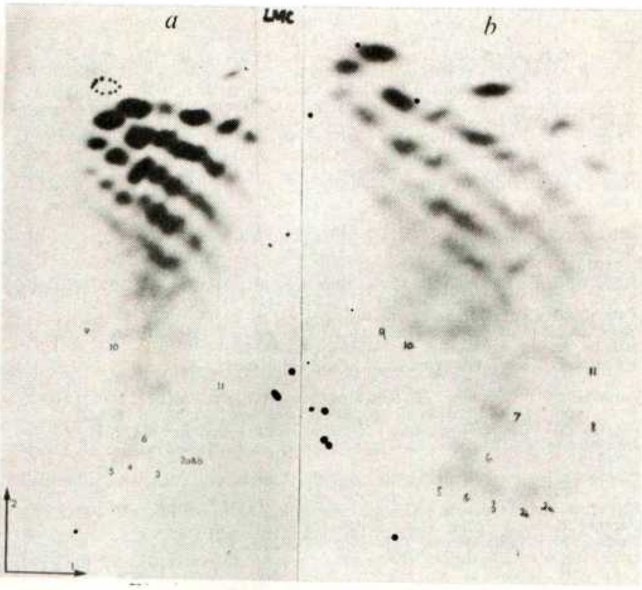

Fig. 5 Comparison of T1 RNase digested coat protein mRNA and 'stable fragment' RNA. ^{32}P-labelled TMV was prepared as described by Zimmern[40] and incubated at 4 °C overnight in 10 mM $NaHCO_3/Na_2CO_3$, *p*H 10.2. Uncoated RNA was digested with micrococcal nuclease (1 μg ml^{-1}) in the same buffer adjusted to *p*H 8.0 with HCl and 1 mM $CaCl_2$. EDTA was added in excess to stop the digestion, and the RNA that had been protected from digestion extracted with phenol–SDS, and purified by sucrose density gradient centrifugation. Fractions containing 'stable fragment RNA' were pooled and precipitated with 2.5 volumes of ethanol. ('Stable fragment' from ^{32}P-labelled TMV was prepared by Michael Wilson.) The precipitate was taken up in 10 mM Tris–Cl, *p*H 7.6, 1 mM EDTA and digested with 3 μl of RNase T1 (1 mg ml^{-1}) in the presence of carrier *E. coli* tRNA (50 μg). The digest was fingerprinted as described by Barrell[44]. Spot 2b is AUAAAUAAUUUAUAGp, which codes for residues 125–129 of coat protein[4]. Spot 5 is AAACCUUCACCACAAGp, which codes for amino acids 53–57[4,21]. Spot 9 is AACCCCACGp, coding for residues 101–103[4]. Spot 4 can also code. Spot 10 here is a mixture, but contains a component giving pancreatic RNase products AAU, Cn, G, chain length 9–10, consistent with AAUCCCCCGp which comes from positions −20 to −28 from the 3′ end of whole TMV RNA (ref. 26). The left hand autoradiograph shows the digest of band 4 extracted from a gel similar to that shown in Fig. 4, except that the RNA was prepared from leaves of plants infected with TMV grown in $^{32}PO_4$. Spots 2a–11 were identified by their pancreatic RNase digestion products as being identical with the equivalent spots in the fingerprint of stable fragment RNA. The more complex appearance of this fingerprint is due to slight pancreatic RNase digestion, which probably occurred during the lengthy extraction process; the mRNA was also slightly contaminated with ribosomal RNA fragments. *a*, Coat protein mRNA; *b*, 'Stable fragment RNA'.

and Knight[27] on the basis of SDS stripping and marker rescue *in vivo*, but agrees with that of Richards *et al.*[28].

Virus replication cycle

On the basis of this evidence, we propose the following account of the replicative cycle of TMV (Fig. 6). After infection of the cell and uncoating of the virion RNA, ribosomes can only translate the cistrons for the 140,000 and 165,000 molecular weight polypeptides, consistent with their early appearance in infected protoplasts. We assume that these functions are required early in infection, and since the subunit molecular weights are close to the apparent native molecular weight of TMV replicase activity in partially purified extracts[29,30], we suggest that both proteins are viral replicases, or their subunits; the function of each being different. For example, one of them may use the (+) strand as a template, the other the (−) strand. Alternatively, one may make coat protein mRNA by partial transcription of the (−) strand, while the other makes full-length transcripts. At least one of them must catalyse the production of complementary copies of the virion RNA, which serve in turn as templates for the synthesis of progeny virion RNA molecules.

The synthesis of coat protein is delayed until its functional mRNA has been produced, because virion RNA does not serve as a template for coat protein synthesis. Two plausible mechanisms for production of the coat protein message are (1) that it is released from virion RNA by specific cleavage, and (2) that it is synthesised by a replicase which initiates transcription at a specific internal site on the complementary strand of TMV RNA. We cannot distinguish between these possibilities at present.

Only when enough coat protein has accumulated to permit the formation of "disk" aggregates[31] can the assembly of virus particles begin[32]. This would delay the encapsidation of virion RNA thereby allowing time for synthesis of early proteins and (−) strands. Once assembly begins the virion RNA will be sequestered and therefore can no longer be a template for either process. But since neither (—) strands nor coat protein mRNA are encapsidated in the case of TMV vulgare, the production of virions can continue for as long as these RNA molecules remain intact, and the replicase(s) active.

This kind of scheme can easily explain how TMV can produce such large quantities of coat protein compared with its other proteins. Being a helical virus, TMV requires many more protein subunits to encapsidate its genome than would a spherical virus with the same genome size[33]. Thus poliovirus, whose RNA is slightly larger than that of TMV, requires only 60 copies[34] of each structural polypeptide compared with about 2,100 in the case of TMV.

Translational control

We do not know why the coat protein cistron is untranslatable in intact TMV RNA whereas it is easily read in the coat protein mRNA; however, at least two precedents offer clues. Initiation of translation of the A cistron of the RNA phages seems to occur only in short growing RNA molecules, since the initiator region of this cistron is involved

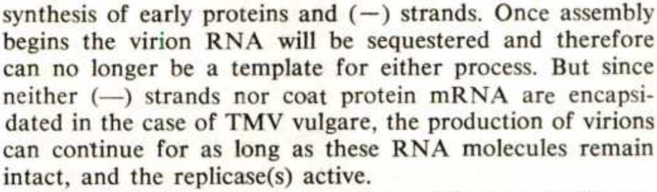

Fig. 6 A tentative map of TMV RNA and its known proteins. The map is drawn to scale. The location of the coat cistron is discussed in the text; the location of the 165,000 and 140,000 molecular weight polypeptides is less certain. Since the sum of their molecular weights exceeds the coding capacity of the virion RNA, they must overlap somehow. We believe they are initiated at different sites since virion RNA can bind two ribosomes simultaneously and independently in the presence of 10^{-4} M sparsomycin, promoting the formation of two methionyl dipeptides: Met–Ala and (probably) Met–Thr (T.R.H. and T.H., unpublished observations). The simplest possibility is that they then terminate at the same site, although this need not necessarily be the case. Their position near the 5′ end of the RNA is suggested by the fact that RNA molecules with small deletions at the 5′ end, constructed by alkali stripping procedures similar to those described in the legend to Fig. 5, fail to synthesise either large polypeptide (T.R.H., M. Wilson, and D.Z., unpublished results). This again is inconsistent with the possibility that the coat protein gene is contained within the large polypeptides (see above). These assignments leave approximately 1,100 residues of RNA unaccounted for, enough to code for up to 40,000 daltons of protein, and this gap has been positioned in the middle of the map. There is evidence from another strain of TMV (the cowpea strain) that a 28,000–30,000 molecular weight protein, whose translation is regulated by a mechanism similar to that described here for TMV coat protein, may be coded in this region[49].

in stable secondary structure in the full-sized RNA molecule[35]. Similar mechanisms may operate in brome mosaic virus (BMV), a multicomponent virus which contains four different RNA molecules. BMV RNA 3 is larger than BMV RNA 4, and just as TMV coat protein mRNA is wholly contained within virion RNA, so BMV RNA 4 is contained within BMV RNA 3 (ref. 36); furthermore, BMV RNA 4 codes efficiently for BMV coat protein, whereas BMV RNA 3 makes another polypeptide but little coat[17]. It seems probable that the coat cistron in BMV RNA 3 is masked by secondary structure, but there is another possibility which may either augment or replace this mechanism. When the sequence of the ribosome binding site of BMV RNA 4 was determined[38], the 5′ end was found to be blocked with m^7G; this unusual end group may be necessary for ribosomes to attach to mRNA[39]. We do not know whether TMV coat protein mRNA has this structure at its 5′ end or not, though intact virion RNA certainly does[40].

Such regulatory mechanisms are not confined to plant and bacterial RNA viruses, however; in both Sindbis and Semliki Forest virus-infected cells small RNAs with the same polarity as the packaged RNA have been found which, unlike their parent molecules, efficiently direct synthesis of the corresponding coat polypeptides *in vitro*[41,42]. Even in the cases of the DNA viruses polyoma and SV40 it seems that larger RNA molecules which code for one protein code for a different protein after cytoplasmic cleavage[43]. Whether such a mechanism regulates the translation of normal cellular messages is unkown. It might account for some cases of 'masked mRNA', for example. We would like to conclude by pointing out that these cases of translational control operate with high efficiency, yet they do not appear to require the action of specific protein synthesis initiation factors.

A preliminary account of these experiments has been published[48].

Clusters of galaxies as gravitational lenses?

KAROJI and Nottale[1] have compared galaxies situated behind or inside clusters with those whose light does not encounter any important cluster of galaxies. They suggested that either light emitted by distant galaxies is redshifted when passing through clusters of galaxies, or distant sources appear more luminous when seen through intermediate clusters of galaxies, which could act as gravitational lenses. Here we examine the magnitude of the lens effect for clusters of galaxies, and find it unlikely that the observational effect claimed by Karoji and Nottale can be explained in this way.

Consider a source of radiation at a distance $L \simeq cz/H_0$ from the observer, in a universe which is homogeneous on some sufficiently large scale, with mean density ρ_u. The line of sight to the source may, however, be such that the mean density along the beam of light, $\langle\rho\rangle$, differs from ρ_u. The cross sectional area, A, of such a beam of light is governed by the equation[2,3]

$$(A^{\frac{1}{2}})'' + 3\alpha\sigma_0(1+z)^5 A^{\frac{1}{2}} = 0 \qquad (1)$$

where $\alpha \equiv \langle\rho\rangle/\rho_u$ is the density enhancement along the beam, $\sigma_0 \equiv 4\pi G\rho_u/3H_0^2$ is the cosmological density parameter, and ′ denotes differentiation with respect to an affine parameter along the beam of light. The solution of equation (1) for such a 'zero-shear' beam shows that a distant source which would have an apparent magnitude m in a strictly homogeneous universe has an apparent magnitude $m+\Delta m$ when seen along this line of sight, where

$$\Delta m = 1.086\sigma_0(1-\alpha)z^2\{1+O(z)\} \qquad (2)$$

It follows that for $\alpha < 1$, there will be a dimming of distant sources[3]. When looking through a cluster of galaxies, however, $\alpha > 1$ and we expect background objects to be intensified.

To estimate the parameter α when the line of sight passes through a cluster, we consider a cylinder of small diameter along the line of sight, and calculate the mean density, $\langle\rho\rangle$, within that cylinder. Since we are interested in clusters of galaxies, we shall use the approximate density law found by King[4] for the Coma cluster

$$\rho(r) = \rho_c\{1+(r/a)^2\}^{-3/2} \tag{3}$$

where ρ_c is the central density, r is the radial coordinate for the spherically symmetric cluster, and a is the distance at which the density has fallen off to $2^{-3/2}\rho_c$. We assume that the cluster has a radius R, defined to be the distance at which the cluster density fades into the universal background density, that is

$$\rho_c/\rho_u = (1+(R/a)^2)^{3/2} \tag{4}$$

For a line of sight with impact parameter Rh, $0 \leqslant h \leqslant 1$, the density enhancement is then found to be

$$\alpha \simeq 1+2\frac{a\rho_c}{L\rho_u}(1-h^2)^{3/2}/\{1+\left(\frac{h}{u}\right)^2\} \tag{5}$$

where $u = a/R \simeq (\rho_u/\rho_c)^{1/3}$.

The intensification, in magnitudes, is then given by

$$\Delta m(h) \simeq -2.172\,(\sigma_c)\frac{a}{c/H_0}z(1-h^2)^{3/2}/\{1+\left(\frac{h}{u}\right)^2\} \tag{6}$$

where $\sigma_c \equiv 4\pi G\rho_c/3H_0^2$ is the density parameter at the centre of the cluster. It is also of interest to obtain the average intensification, $\langle\Delta m\rangle$, over the area of the cluster

$$\frac{\langle\Delta m\rangle}{\Delta m(0)} = u^2\{(1+u^2)^{3/2}\ln\left(\frac{(1+u^2)^{\frac{1}{2}}+1}{(1+u^2)^{\frac{1}{2}}-1}\right)-2u^2-\frac{8}{3}\} \tag{7}$$

For this approach to be valid, the focal length, $f(h)$, of the gravitational lens must be significantly larger than the source–lens and observer–lens distances, and it must be assumed that the cluster lies roughly halfway between source and observer. The last restriction is not very stringent, for roughly halfway means really that neither the source nor observer lies right next to the cluster when compared to the other.

The angle of deflection for photons passing the lens at a distance Rh from its centre is given by

$$\theta(h) = 4GM_c(h)/c^2Rh \tag{8}$$

where $M_c(h)$ is the mass contained within the cylinder, of radius Rh, whose axis passes through the centre of the lens, parallel to the line of sight[5]. By considering radially adjacent lines of sight with impact parameters Rh and $R(h+\mathrm{d}h)$, the focal length is found to be

$$f(h) = R\left(\frac{\mathrm{d}\theta}{\mathrm{d}h}\right)^{-1} = \frac{c^2R^2}{4G}\left\{2\frac{\mathrm{d}M_c}{\mathrm{d}(h^2)}-\frac{M_c}{h^2}\right\}^{-1} \tag{9}$$

For the King density distribution, we find

$$M_c(h) = 4\pi a^3\rho_c\left\{\ln\left(\frac{(1+(1+u^2)^{1/2})(1+(h/u)^2)^{1/2}}{(1-h^2)^{1/2}+(1+u^2)^{1/2}}\right) - \frac{1-(1-h^2)^{1/2}}{(1+u^2)^{1/2}}\right\} \tag{10}$$

which gives for the focal length of such a lens

$$\frac{f(h)}{f(0)} = \left(\frac{1}{2}\right)\left(\frac{h}{u}\right)^2\left\{1-\frac{(1-h^2)^{1/2}}{1+(h/u)^2}-(1+u^2)^{1/2}\times \times\ln\left(\frac{(1+(1+u^2)^{1/2})(1+(h/u)^2)^{1/2}}{(1-h^2)^{1/2}+(1+u^2)^{1/2}}\right)\right\}^{-1} \tag{11}$$

where

$$f(0) = \frac{(c/H_0)^2}{6\sigma_c a}(1+u^2)^{1/2}$$

is the focal length through the centre of the lens.

If we adopt the parameters given by King for the Coma cluster (noting that he used $H_0 = 75$ km s^{-1} Mpc^{-1}), we then find $\sigma_c = 2.1 \times 10^4$. It follows that for this cluster $f(0) \simeq 750$ Mpc and $\Delta m(0) = -1.94z$, where z is the redshift of the source observed through the cluster. Since the mean radial velocity of the objects found by KN to lie behind clusters is 11,600 km s^{-1}, the average intensification of such an object observed through the centre of the Coma cluster should be $\overline{\Delta m(0)} \simeq -0.076$ mag. Objects not observed through the centre of the cluster will, of course, be less intensified, as indicated by equation (6). If the object being observed lies inside the cluster, there will be a range of α depending upon the position of the object, and hence a greater range of Δm. In fact, a proper treatment of this case would require a detailed knowledge of the parameters of the cluster and the position of the source within it, but we think it unlikely that the maximum intensification would be more than a factor of two different from $\overline{\Delta m(0)}$ above.

Our value of $\overline{\Delta m(0)}$ is considerably less than the mean magnitude differences (-0.26 ± 0.218 and -0.43 ± 0.237) found by Karoji and Nottale, although their error limits are large. It must also be remembered that many of their objects are being seen through clusters which are considerably smaller, and presumably less condensed centrally, than Coma. This suggests that, if the large magnitude differences found by Karoji and Nottale are real, then 'gravitational lensing' is unlikely to be the cause.

Because galaxy magnitudes are notoriously difficult to measure precisely, we suggest, however, that it may be worthwhile to make an accurate, systematic investigation of the apparent magnitudes of a homogeneous, distant sample of galaxies seen through, and outside of, a cluster of galaxies such as the Coma cluster. The general theory of relativity predicts that the lensing effect must be present; our calculation indicates that measurements with an accuracy of ~0.01 mag will be necessary to find it. This is clearly at the limit of accuracy obtainable in measurements of galaxy magnitudes[6]. If the effect were found, however, it would provide not only further verification of general relativity, but also a means of probing the mass of a cluster of galaxies, independent of assumptions about the mass to luminosity ratio of its constituents.

Decametric radio emission from four pulsars

We have reported earlier[1] on the reception at low radio frequencies of radio pulses from three pulsars. A similar method[2] was used during 1973–74, and four more pulsars were detected.

The signals were fed into 16 receivers with analog stores giving an equivalent time constant of 100 s. The receiver central frequencies and bandpass values were chosen to allow for frequency dispersion, giving a time resolution of $T/16$, where T is the period of the pulsar. The source was tracked for periods of 1–5 h during the measurement. Stored signals were recorded at intervals of 180–200 s.

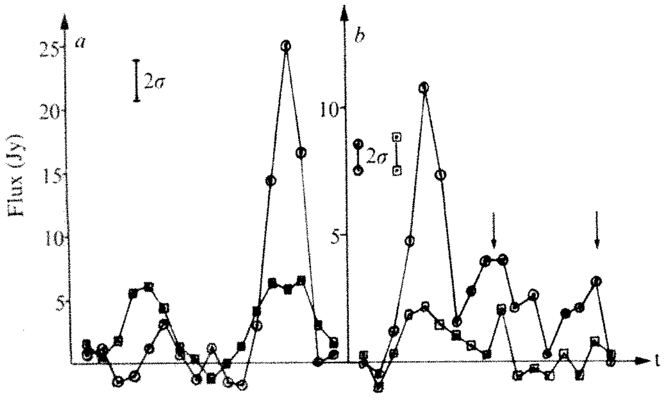

Fig. 1 Integrated pulse profiles for PSR0950+08. *a*, For 1973 March 27, taken over 2,400 pulses. *b*, For 1973 March 1, taken over 23,000 pulses at 25 MHz and 16,000 pulses at 20 MHz. ⊙, 25 MHz data, at 80 kHz bandwidth; □, 20 MHz data at 40 kHz bandwidth.

The signals were averaged over time as well as frequency channels. The signals from the separated frequency bands were superposed with a time delay calculated from known values of the dispersion measure.

At low radio frequencies the integrated pulse profiles are wider than at high frequencies, and they contain new components (interpulses). We distinguished these components from noise by setting a threshold level which depended on the r.m.s. noise level, taking account of the width of the components and the error in determining the mean flux[3]. Some observational results are presented in Table 1, together with the main parameters of the equipment.

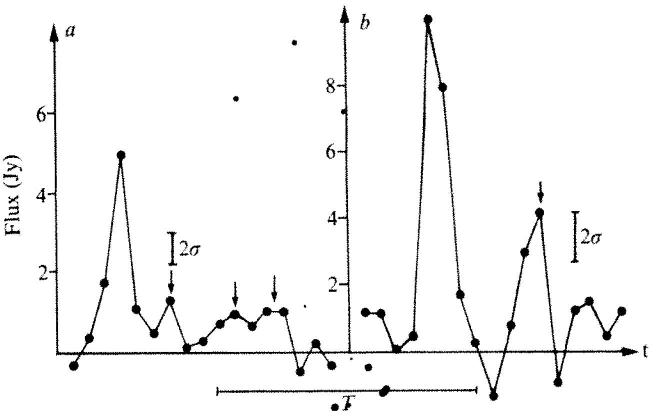

Fig. 2 Integrated 25 MHz pulse profiles for PSR0834+06. *a*, 3,000 pulses on 1973 March 7 and 1973 March 27 at 160 kHz bandwidth. *b*, 1,700 pulses on 1973 April 17, at 80 kHz bandwidth.

PSR0950. As at higher frequencies this pulsar shows a high sporadicity. Shown in Fig. 1 are two typical repeated forms of the integrated pulse profile, recorded at 25 MHz and at 20 MHz. In this and the following figure the 2σ noise level is shown. The main pulse is followed either by one interpulse at $0.4T$ (Fig. 1*a*) or by two at $0.3T$ and $0.7T$ (Fig. 1*b*), which overlap and cover the entire period. This behaviour may be compared with the interpulse observed at high frequencies[4,5], which occurs $0.6T$ after the main pulse.

PSR0834. This pulsar has a lower intensity and it was detected only at 25 MHz. Its integrated profile is very complex (Fig. 2). For 50 per cent of cases it showed an interpulse $0.4T$ after the main pulse; two more interpulses appear rather seldom. The points of minimum emission are stable.

PSR1237. Both this pulsar, and PSR2016, are characterised by a high sporadicity and low intensity. Figure 3 shows two typical

Fig. 3 Integrated 25 MHz pulse profiles for PSR1237+25. *a*, Taken from 1,200 pulses on 1973 January 17: — 110 kHz bandwidth, - - - 110 kHz bandwidth, **—** 220 kHz bandwidth. *b*, 800 pulses on 1973 February 7: — 110 kHz, - - - 110 kHz, **—** 220 kHz bandwidths. *c*, 1973 April 4: — 110 kHz; 1973 April 10: - - - 110 kHz bandwidth; combined data: **—**, 500 pulses. *d*, 1973 March 29: 1,800 pulses; — 110 kHz, - - - 110 kHz, **—** 220 kHz bandwidths.

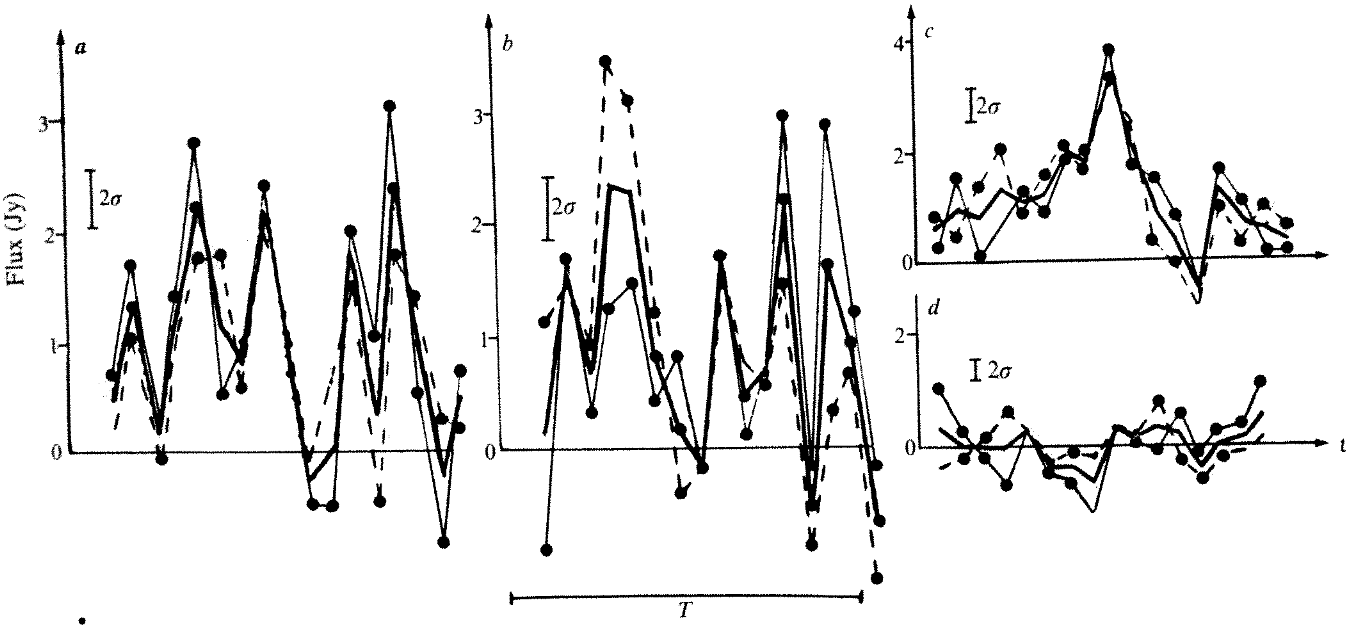

Table 1 Observational results

PSR	Frequency range (MHz)	Band of 1st channel (kHz)	Detuning between the adjacent channel (kHz)	Average flux $\times 10^{26}$ (W m^{-2} Hz^{-1})	No. of interpulses	Width of the main pulse (ms)
0834	25	10	12.00	0.94	0–4	130
0950	25	8–10	9.94	1.7	0–2	35
0950	20	4–5	5.19	0.75	1–2	65
1237	25	14	17.19	1.0	0–4	—
2016	25	4	4.63	0.2	1	35

integrated profiles obtained at different times. Some features are common to Fig. 3*a* and *b*, and to Fig. 3*b* and *c*, but there are obviously very large differences. Figure 3*d* shows a corresponding record when the pulsar signal was not observed.

PSR2016. The integrated profile is shown in Fig. 4. Again the profile is complex, showing a main pulse and an interpulse.

An important conclusion can be drawn from these results and from those of our earlier investigation[1]. The integrated pulse profile, or 'emission window', for all of the seven pulsars so far investigated, covers almost the entire period and contains intense interpulses. This effect seems to be a typical behaviour of the decametric radio band.

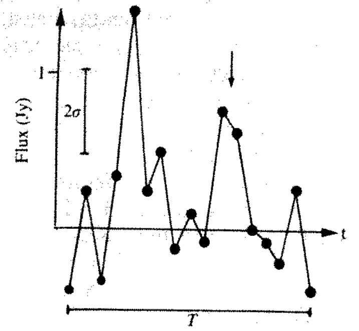

Fig. 4 Integrated 25 MHz pulse profile for PSR2016+28. 10,000 pulses taken on 1972 October 3 at 64 kHz bandwidths.

We thank Professor S. Ya. Brande, Dr N. A. Sapagova and V. C. Sinitsin for their help.

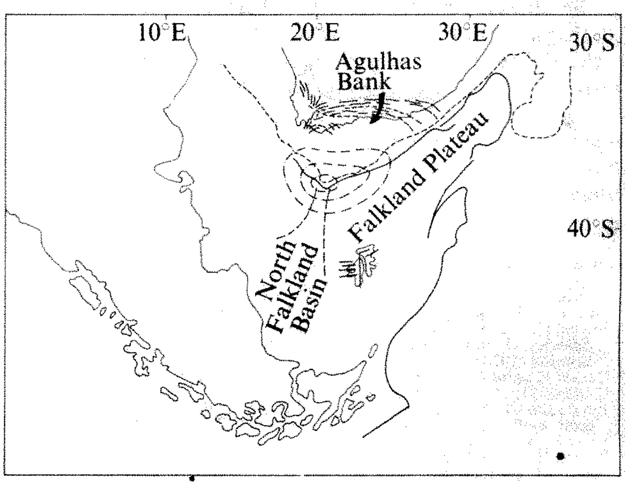
Was there an Agulhas triple junction?

Discussions on the opening of the South Atlantic in terms of major plate tectonic structures such as spreading ridges, transform faults, and so on, have tended to concentrate on the West African segments[1-3]. Evidence has been presented for regarding the original break in the Gulf of Guinea as an RRR junction, the southward-trending arm becoming the Mid-Atlantic Ridge, the north-east-trending arm (Benue Trough) undergoing a relatively minor phase of opening followed by closing, and the westward arm becoming modified by a series of oblique shears so that movement there became a combination of spreading and transform motion (ref. 1, Fig. 1). An analogous set of movements was proposed for the Red Sea, Dead Sea, Gulf of Suez junction. Later, a large number of other triple junctions was recognised[4], including a Georgetown RRR junction to the west which helped to define the course of the Africa/South America split and left the Takutu rift in Guyana as a failed arm filled with Cretaceous deposits.

So far, little attention has been paid to the southern end of the Atlantic spreading ridge in the reconstructions of the breakup of Gondwanaland, although the presence of a major transform (the Agulhas/Falkland Fracture Zone) is now well established. Little is known in detail about the Falkland Plateau, but the presence of the Falkland Islands, and the granitic basement found by deep drilling[5] strongly suggest that the whole plateau consists of continental crust. Assuming this to be the case, and taking the 2,000-m isobath as defining the plateau edge, it is possible, using a slightly modified Bullard rotation, to fit the Falkland Plateau into the embayment of the distal Natal Valley, between the Agulhas Fracture and the southern Mozambique Ridge, with very little gap or overlap (Fig. 1). The South Atlantic spreading ridge and the Agulhas Fracture meet at approximately a right angle, and as Burke and Dewey[4] have suggested that such angular bends commonly mark the site of triple junctions, it is worth enquiring whether a third arm exists. There is, in fact, evidence of a trough almost bisecting the angle made by the two other fractures; this is the North Falkland Basin, the present-day trend of which is north-east, and which lies north-west of the Falkland Islands. This contains[6] up to 2 km of sediments, mainly of suggested late Cretaceous age.

Thus it is possible to postulate a triple junction consisting of the Atlantic spreading ridge, the Agulhas Fracture, and the North Falkland Basin—that is, a spreading ridge, a transform fault, and a failed arm—and it is proposed that this be called the Agulhas Triple Junction

Fig. 1 Proposed Agulhas Triple Junction, showing schematic contours of uplift (–·–) and relationship to the Cape Fold Belt.



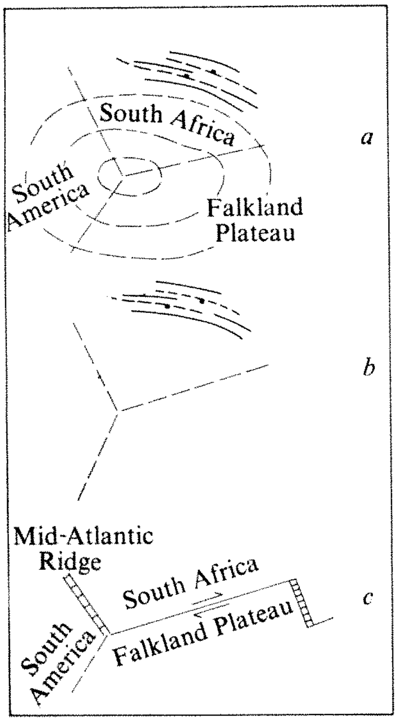


Fig. 2 Schematic representation of the proposed evolution of the Agulhas Triple Junction. *a*, Uplift and doming, radial and concentric fractures, formation of the Cape Fold Belt (early Triassic); *b*, subsidence with reversal of throw on Cape faults, no spreading, (?) initiation of Mesozoic basins (Triassic to Jurassic); *c*, initiation of separation, further faulting in Cape Fold Belt (early Cretaceous).

(Fig. 1). The similarity to the examples of the Gulf of Guinea, Georgetown and the Gulf of Suez is clear.

The idea of a possible Agulhas triple junction arose from studies in the Cape Fold Belt[7], which resulted in the proposal of a gravity sliding model for the development of that orogen. This required that uplift should take place south of the present Fold Belt to form the slope on which sliding was initiated, and it was found that uplift centred on the proposed junction was well situated to do that. Since the initiation of triple junctions seems to depend on the strain developed over an uplift, probably resulting from a rising mantle plume[4], it seemed natural to link the two concepts (Fig. 2). Upwelling must have been followed by subsidence (since no spreading occurred at this stage), which led to major southward downthrow on the large longitudinal faults associated with the Cape Fold Belt, and possibly also to the initiation of the Mesozoic basins of the South African continental shelf and coastal areas, which contain sediments as old as Triassic[8]. Separation only occurred later (125–130 Myr)[9] but could have been controlled by the directions of the earlier-formed fractures.

I thank Professor R. V. Dingle for drawing my attention to the existence of the North Falkland Basin, and to C. J. Hartnady for the Bullard reconstruction.

Shortening of continental crust in orogenic belts and plate tectonics

THE geotectonic and palaeogeographic problems created by severe crustal shortening in orogenic belts are numerous and difficult to solve. In spite of plate tectonics, or because of it, one such problem of major significance persists: where is much of the continental crust that once underlay many of the nappes in tremendously shortened and imbricated belts such as the Alps[1–4]? In the scheme of plate tectonics, it is implausible to pull, melt or shove continental crust back into the mantle[5]; yet some authors express faith in such a concept[6] or, lacking faith, despair of a solution[7]. I propose that the solution to this problems lies quite simply in the fact that the original eugeosynclinal basement[8] of the Alpine belt consisted of distended continental crust, as clearly understood by Trümpy[9].

It is possible to calculate the crustal shortening in the Eastern Alps by assuming constant crustal volume through time. The present crustal volume may be measured from a crustal model of the Eastern Alps based on detailed gravity and seismic studies[10]. In agreement with Dewey *et al.*[11], I assume that the volume of continental crust measured in the Alpine geophysical profiles is a reasonable approximation of the original volume of continental crust that existed before development of the Tethys and the Pennine Trough as well as before Alpine deformation. Crustal additions and subtractions from and by the mantle, the oceanic crust, and erosion and sedimentation (and also by volume changes) are thus considered relatively insignificant or mutally cancelling for the purposes of my calculations. The assumption of no crustal addition may not be far fetched, at least for the eastern Alps, considering the paucity of Mesozoic–Cainozoic magmatism and ophiolites in the area. The assumption of no crustal subtraction by erosion is clearly wrong for the Alps, but the evaluation of erosional losses would only amplify the conclusions of this study, and thus erosion is ignored. The assumption of no crustal subtraction by 'oceanisation' or disappearing continental blocks is reasonable, and is the principal point shown here.

Figure 1 shows the total measured crustal volume of a 1-km-thick slice of the 222-km-long profile to be 9.640 km^3. with an average crustal thickness of 43.4 km. (For this calculation, made with a polar planimeter, I have subtracted out the chemical contribution of the volume of the Mesozoic carbonate rocks in the Northern Limestone Alps.) Assuming an initial normal crustal thickness of 30 km, it follows that an initial length of section of 321 km would be required to maintain constant volume. This would require a shortening of nearly 100 km in the present state. This number does not compare with geological estimates of 180–600 km of shortening[1,3,4] of the palaeogeographic realms underlain by continental crust in the Eastern Alps.

The Red Sea region can be used as a valid geotectonic model of the Triassic–Jurassic Alpine belt, representing an initial crustal configuration in which palaeogeographic realms are sited on distended continental crust (see refs 12 and 13). From the profile (Fig. 2), a simple analysis as described in Fig. 3 results in the values shown in Table 1.

Table 1 Parameters from Red Sea and Alpine regions

Length of Red Sea profile	449 km
Shorten profile to subtract all oceanic crust	−82 km
Shorten to restore continental crust to original thickness (30 km thick)	−146 km
Shorten to thicken continental crust to 43.4 km average of present Eastern Alps	−69 km
Final width of the profile	152 km

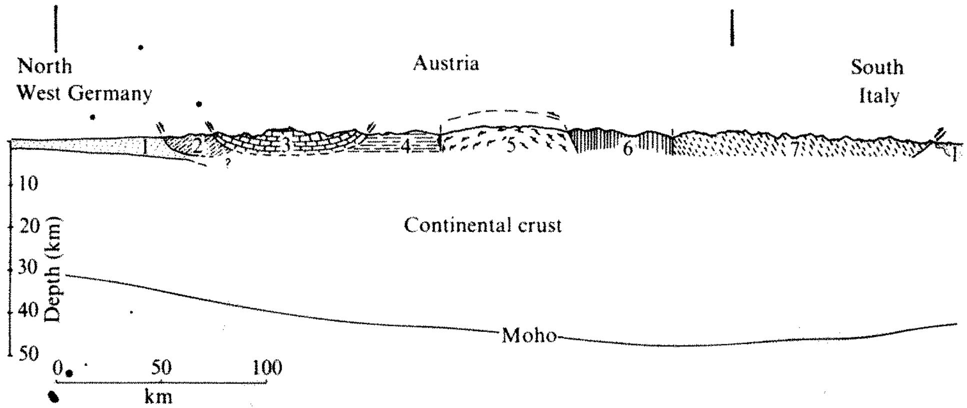

Fig. 1 Crustal profile through the eastern Alps from near Chiemsee, West Germany (north), in the molasse zone, to Maniago, Italy, in the Po Basin (adapted from Angenheister *et al.*[10]). 1, Molasse; 2, flysch and Helvetic zone; 3, Northern Limestone Alps; 4, greywacke zone; 5, Tauern fenster; 6, Altkristallin; 7, Southern Alps.

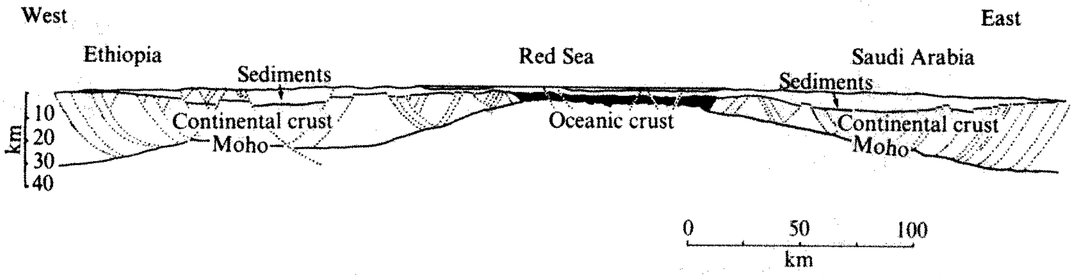

Fig. 2 Crustal profile through the southern Red Sea from Ethiopia (west) to Saudi Arabia, based upon gravity, seismic, magnetic and bore hole data (adapted from Lowell and Genik[12]). The extreme thinning of continental crust shown in this profile is not agreed upon by all workers, but is considered to model the Alpine region in the Triassic–Jurassic. This profile is not entirely perpendicular to regional strike. In calculations, the sediments are not included in the volume of continental crust in as much as they are largely chemical precipitates.

Assuming the effective removal of the oceanic crust without trace, the shortening of the continental crust is 215 km.

In order to attain the final dimensions of the Alpine profile for direct comparison, I have added 70 km of length to reach 222 km (Fig. 1) Since this 70 km must have a final thickness of 43.4 km, it is actually necessary to add 100 km of crust 30 km thick to the initial profile (Fig. 2). That is, the Alpine crustal profile balances in volume with a Red Sea profile that includes an extra 100-km-long stretch of normal continental crust beyond that shown in Fig. 2. Therefore, the final dimensions of the crustal shortening model developed are as shown in Table 2.

Table 2 Dimensions in the crustal shortening model

State	Dimensions of profile
Initial stage of continental distension (Red Sea model)	549 km long (82 km oceanic length) 9,640 km^3 per km continental crust Continental crust varies from 0 to 30 km thickness
Final stage of orogenic shortening (Eastern Alps)	222 km long 9,640 km^3 per km continental crust Continental crust 43.4 km average thickness 245 km of crustal shortening on continental basement

This model of crustal shortening, though based on gross and simplifying assumptions, seems to provide an explanatory step in the right direction. For, along with a geologically reasonable estimate of crustal shortening over continental basement (245 km), it also eliminates the need for disappearance of large volumes of continental crust, a concept distasteful to fundamental physical principles. The problem of excessive crustal shortening in orogenic belts may, therefore, be eliminated on consideration of the simple fact that initial thinning of continental crust of orogenic belts has not until now been taken into account in models of crustal shortening.

Of course, I am aware that many factors contribute to changes of crustal volume and that the deformation of colliding continental blocks, in particular, must be complex in space and time[14–16]. This paper serves only to emphasise the critical importance of initial crustal configuration when considering problems of orogenic crustal shortening. The application of this result to the study of orogenic tectonic evolution will be of interest.

I am grateful to Professor A. Tollmann for his assistance and for providing a Gastdozent position at the University

Fig. 3 Method of calculation. The crustal volume in profile of two rifted continental margins (*a*) is set equal to the crustal volume of the orogenic profile (*b*). Knowing the length L_2, L_1 can be calculated to satisfy the balance $V_A + V_B = V_C$. The amount of shortening on continental basement is $L_1 - L_2$. The horizontal dimension of any oceanic crust in profile (*a*) is eliminated because it and its overlying sediments (except chemical sediments that must be subtracted) cannot enter into the crustal balance as discussed in the text.

Biostratigraphy of some marine manganese nodules

Using scanning electron microscopy (SEM) we have examined the microtexture of Mn nodules. Previous researches using SEM observation on marine Mn nodules have revealed many characteristic features which may relate to their formation[1–6].

We report here the discovery of *in situ* calcareous nannoplankton fossils in a Mn nodule collected during the RV Hakuho-Maru Cruise KH-74-4, and present a preliminary calculation of the growth rate, using a biostratigraphic method. We also discuss the potential value of Mn nodule biostratigraphy[7] in terms of deep sea palaeoenvironments.

The Mn nodules were dredged from a brown clay by a Norwalk type dredge at the summit of Makarov Guyot (29°26.3′N, 153°27.3′E; water depth, 1,378 m)[8]. One of them (16002) is spheroid in shape, with concentric symmetric layers around a basaltic rock nucleus (Fig. 1*a*). The crust, about 60 mm thick, comprised three layers: an outermost, 2 mm thick with a bumpy surface texture (Fig. 1*b*); a middle, about 8 mm thick, comprising many thin lamellae; and the innermost, about 50 mm thick, massive and dense in texture.

The outermost layer and the innermost layer adjacent to the nucleus were peeled off by hand after drying at room temperature, and were coated with carbon and gold thin films for SEM observation.

The ooze adhering to the surface of the outermost layer comprised calcareous nannoplankton fossils: *Coccolithus pelagicus* (Wallich) Schiller; *Cyclococcolithina leptopora* (Murray and Blackman) Kamptner; *Emiliania huxleyi* (Lohmann) Hay and Mohler; *Gephyrocapsa oceanica* Kamptner; and *Umbilicosphaera mirabilis* Lohmann. The assemblage represents NN21 zone (0.2 Myr–present)[9].

The surface of the outermost layer itself is also covered with calcareous nannoplankton fossils. The microtexture and the presence of *E. huxleyi* (Fig. 1*c*) indicate the recent growth of the nodule.

The inner surface of the outermost layer also contains calcareous nannoplankton fossils preserved as impressions (Fig. 1*d*) or replaced by ferromanganese oxides (Fig. 1*f*). Although most are too poorly preserved, several species have been identified: *C. pelagicus; Cyclococcolithina macintyrei* Bukry and Bramlette; *Cyclococcolithina leptopora; Pseudoemiliania lacunosa* (Kamptner) Gartner; and *U. mirabilis*. The assemblage indicated NN19 zone (2–0.5 Myr). The presence of a coccosphere of *Cyclococcolithina leptopora* (Fig. 1*d*) suggests that the fragile coccosphere itself may have been covered with ferromanganese oxide soon after the deposition on to the nodule surface, which subsequently dissolved away after consolidation of the oxide. Likewise, the other microfossils are considered to have been rapidly incorporated into the layer, probably simultaneously with the ferromanganese oxide. Besides the late Neogene calcareous nannoplankton fossils, several individuals of *Chiasmolithus grandis* Hay, Mohler and Wade (Fig. 1*e*), an Eocene index species, were found inside a cavity in the outermost layer. Since, unlike the other *in situ* microfossils, they were observed only in the cavity,

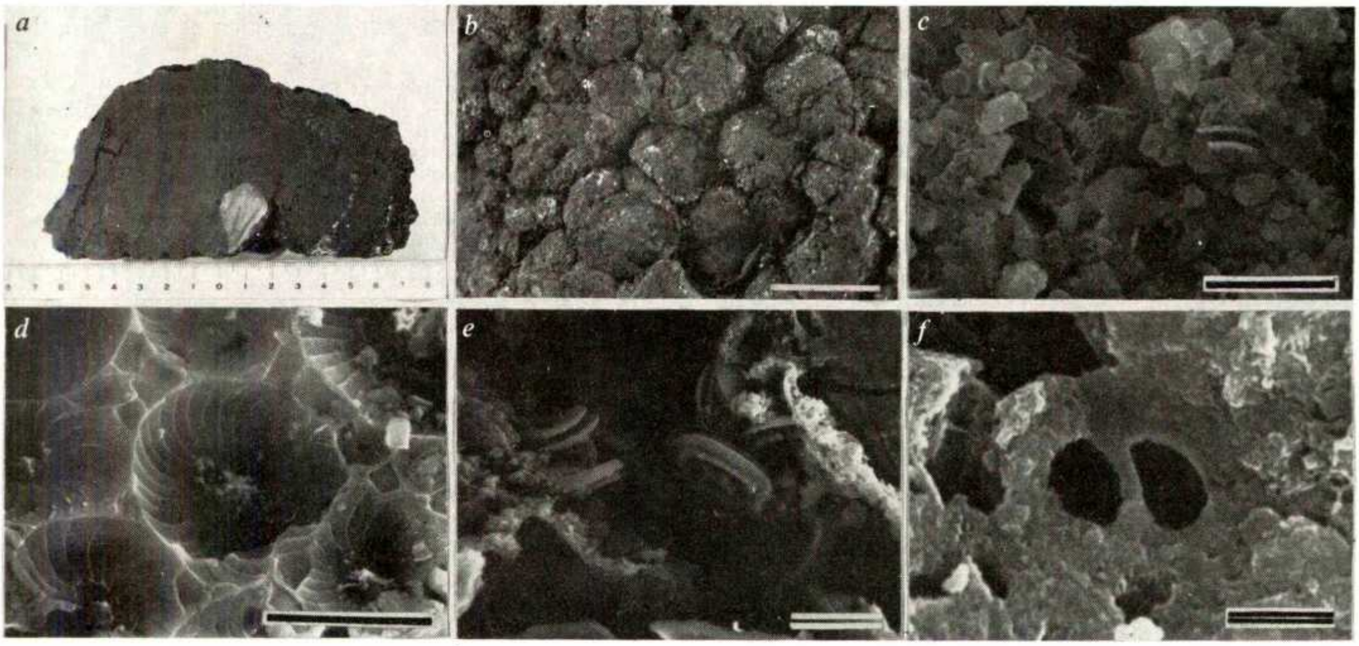

Fig. 1 Photographs (*a*, *b*) and SEM photomicrographs (*c*–*f*) of a marine Mn nodule. *a*, Tangential section showing three major layers: thin outer layer; middle layer with many thin lamellae; and massive innermost layer (scale, 1 cm). *b*, Detail of the surface texture of the outermost layer. Bumps were peeled off for SEM observation (scale, 1 cm). *c*, Enlarged surface texture of the outermost layer after ultrasonification. *E. huxleyi* embedded in the layer indicates the recent growth of the nodule (scale, 5 μm). *d*, Impression of a coccosphere of *Cyclococcolithina leptopora* suggesting that most of the microfossils were incorporated into the layer rapidly (scale, 5 μm). *e*, *Chiasmoliuths grandis* (scale, 20 μm). *f*, *G. oceanica*, replaced by Mn oxides, in the innermost layer adjacent to the nucleus (scale, 1 μm).

apparently unaltered, they may have resulted from the reworking of the sediments.

In the innermost layer adjacent to the nucleus, *G. oceanica* (Fig. 1*f*), which first appeared at the beginning of the Pleistocene, were observed. No specimens of *Discoaster*, a species which became extinct at the end of the Pliocene, were found. Greenslate has suggested an important role for siliceous microfossils in nodule formation[4]; however, we have not recorded significant amounts of siliceous fossils (see refs 5 and 6).

Since the calcareous nannoplankton fossils preserved in the layers record the age of each layer, we can calculate the mean growth rate of each layer; other methods[10–14] only give that of the outer layer.

The assemblages of the outermost layer indicate that it started to grow 2–0.5 Myr ago, and that it continued at least until 0.2 Myr ago. The mean growth rate of the outermost layer is thus 1.0–6.7 mm Myr^{-1}. The values calculated are compatible with those obtained by conventional methods: 1–100 mm Myr^{-1} (ref. 15).

On the other hand, the presence of *G. oceanica* and the absence of the members of *Discoaster* in the innermost layer adjacent to the nucleus suggest that the nodule is younger than 2 Myr old. Therefore, the minimum mean growth rate of the nodule, except for the outermost layer, is 39 mm Myr^{-1}. That seems reasonable, though it is about 5–40 times higher than values obtained from the outermost layer. The massive texture of the innermost layer may reflect a rapid growth. Further study of the intermediate layers is needed to verify the hypothesis.

The discrepancy between the two growth rates suggests an irregular rate of accretion not considered in previous work[12]. This hypothesis is supported by the nature of the surface texture and by the presence of coccospheres. As the accretion rate of marine Mn nodules is considered to relate intimately to low sedimentation rates and to the water current on the sea floor[15], the drastic change of rate may correspond to a change in the deep-sea environment in the region during the late Pleistocene.

If the assemblage of microfossils in the layers of Mn nodules can be correlated with those in the sedimentary sequence of the same region, more information on both the origin of the nodules and on the regional palaeoenvironment of the deep sea should be provided.

This work was financially supported in part by the Ocean Research Institute, University of Tokyo. We thank Professor N. Nasu for offering the opportunity to join the Hakuho-Maru Cruise KH-74-4, Dr E. D. Goldberg, Scripps Institute of Oceanography, for help with the manuscript, and Professor T. L. Ku, University of Southern California, for critical comments.

Climatic implications of stable carbon isotopes in tree rings

STABLE carbon isotope variations in tree rings are normally attributed to either a direct temperature dependent fractionation process in the tree[1], or alternatively to variations in atmospheric composition[2,3]. To clarify this apparent conflict we have begun measurements of ratios in rings of Southern Hemisphere trees. In spite of some obvious differences between the two trees studied so far, both show a positive correlation with regional temperature trends over the past 75 yr. This result is discussed in terms of the alternatives above, and with the view of extracting palaeoclimatic information. Verification of such influences could provide > 2,000 yr of data on the climate of the region.

Five-year blocks were taken from two King Billy pines (*Arthrotaxis selaginoides* D. Don) which grew within 200 m of each other in natural forest in mountains of northern Tasmania (Fig. 1). A total of 71 separate burns were made on the 25 5-yr blocks of one tree and the CO_2 from each burn analysed at least twice. The δ^{13} variations for each block were generally < 0.1‰. The second tree had 31 5-yr blocks and 50 burns were performed. A full discussion of the experimental technique, tree environment and dendrochronology, and raw data will be published elsewhere.

Variations of 0.2–0.3‰ in δ^{13} are observed in consecutive blocks but these are not always duplicated in the two trees. On a longer time scale, however, similar major trends are evident in both trees, a decrease in δ^{13} from 1895 to ~ 1945 and a rapid increase back to the 1895 level by 1970. This is

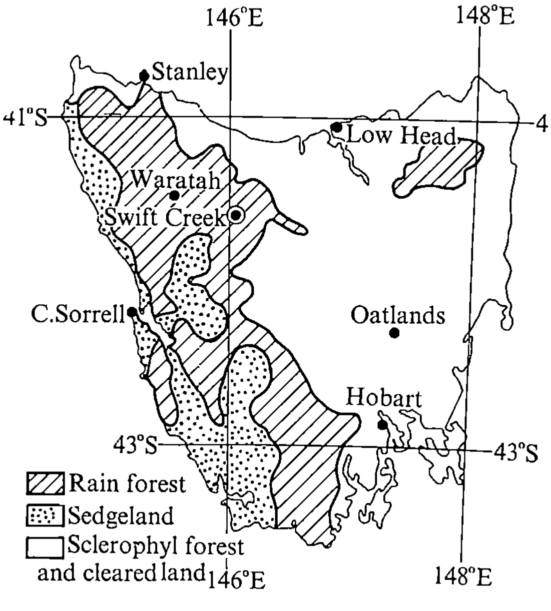

Fig. 1 Map of Tasmania showing the location of the six climatological stations and the Swift Creek site from which the study trees were obtained. Representative samples of 25–75 mg from each block were burnt in an oxygen atmosphere similar to that described in ref. 4 The resulting CO_2 was cryogenically trapped and its isotopic composition analysed using a Micromass 602B mass spectrometer. Results are reported in conventional δ^{13} units, where

$$\delta^{13} = \left[\frac{(^{13}C/^{12}C)_{\text{wood}}}{(^{13}C/^{12}C)_{\text{standard}}} - 1\right] \times 1{,}000(‰)$$

A cylinder of CO_2 was used as a standard and by adding an arbitrary −8.0‰ our data were made comparable to the PDB standard The influence of solvent extraction, cellulose separation and variations in oxygen isotopes were found to be of similar magnitude to those reported elsewhere[5–8], relatively constant throughout heart and sapwood, and incapable of significantly influencing the long term trends observed. Thus the bulk of the measurements were on whole wood samples.

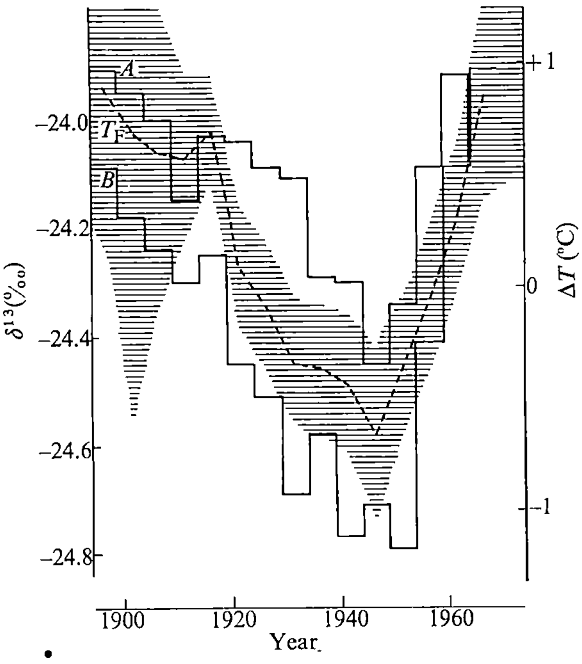
illustrated in Fig. 2 which gives δ^{13} histograms for each tree. The large block-to-block variations have been partly suppressed with a 3-block (15-yr) running mean.

Corresponding 5-yr blocks (means) of ring width, rainfall and temperature data have been analysed and correlated with the δ^{13} curves. The only significant correlations (5% significance level as indicated by the Student's t test) are with maximum temperatures. The correlation coefficients improve with the 3-block smoothing, and also consistently and significantly as the temperature data are restricted to summer months, particularly February. Convective mixing in the lower atmosphere during the daytime ensures that maximum temperatures are far less susceptible to local influences than are minimum (and thus mean) temperatures. Thus maximum temperatures will be more influenced by, and therefore more highly correlated with, the mean temperature of a larger volume of the atmosphere, particularly in summer, when convective activity is greatest. It may also be important that January and February maximum temperatures more closely represent times of tree growth. In Fig. 2 the pecked curve represents the 3-block running mean of February maximum temperatures for six stations surrounding the tree location (Fig. 1). The consistent long term behaviour of all stations (and, by implication, the tree site) is indicated by the shaded area which encompasses the standard deviations obtained by averaging the normalised deviations from the mean for each station. Similar temperature trends are suggested by data of Coughlin[9] for 9 provincial towns in SE Australia, by sea surface measurements east of Tasmania (D. J. Rochford, personal communication), and also by recent data for New Zealand[10].

A regression analysis of δ^{13} against temperatures for the curves of Fig. 2 gives temperature coefficients of 0.48 ± 0.12 and $0.24 \pm 0.11\%\ ^{\circ}\mathrm{C}^{-1}$ for trees B and A respectively. The correlation between unsoothed temperature and mean tree data is significant to the 1% level.

A temperature dependent fractionation process during photosynthesis with a theoretically derived coefficient of $0.36‰\ ^{\circ}\mathrm{C}^{-1}$ has been proposed by Libby[12], and supported by a comparison between the δ^{13} trends in a German oak and Western European temperature variations. The comparison is far less convincing than those in Fig. 2 and gives a temperature coefficient which is now known to be overestimated[7]. Laboratory investigations of a temperature fractionation effect in non-arboreal species[2,11] generally show an effect very much smaller and of opposite sign to those reported here.

Fig. 2 Smoothed deviation (ΔT) from the long term average of February maximum temperature for six Tasmanian stations and the δ^{13} of trees A and B.



Freyer and Wiesberg[2,13] have summarised their own extensive measurements[7], plus those of Farmer and Baxter[3], relating to δ^{13} values in Northern Hemisphere tree rings. From trees selected as representing carbon exchange with the free atmosphere, a common δ^{13} pattern has emerged. It falls ~0.5‰ between 1905 and 1940, rising ~0.3‰ by 1960 and falling 0.3‰ thereafter. Both sets of authors propose that the trees are registering variations in the isotopic composition of the atmosphere. Dilution of atmospheric ^{13}C by the release of biospheric CO_2 accompanying increased land cultivation is identified with a sharp fall early in the century, and fossil fuel combustion accounts for only a small overall decrease. Climatic variations possibly acting through ocean and biomass exchange are mentioned as possible contributing factors. Correlation coefficients between the tree ring data of Fig. 2 and those described above are ~0.5, and scarcely significant at 5%. Over the years 1905 to 1940–50, however, the similarity is more pronounced.

Much of the δ^{13} variation and the similarity could be accounted for by CO_2 exchange with the temperate oceanic mixed layer as the result of temperature changes. Freyer and Wiesberg[2] calculate a change in δ^{13} in the atmosphere of +0.3‰ for each 1 °C temperature increase. The exchange would be dominated by long term temperature variations in the Southern Hemisphere whose oceans contain 80% of the total temperate mixed layer. The regional temperature variations shown in Fig. 2, however, may not be representative of the hemisphere because of a lack of spatial coherence of temperature variation on a sub-hemisphere scale[14]. For the same reason, we cannot dismiss the possibility that similarities in δ^{13} variations in both hemispheres may have resulted from the fortuitous occurrence of similar temperature trends in the regions from which trees were collected. The Freyer and Wiesberg and the Farmer and Baxter trees may have responded directly to regional temperature trends which were different to those accepted for the Northern Hemisphere as a whole[15].

Whatever the cause, the tree analyses reported here show a significant correlation with regional temperature on a time scale longer than 5–10 yr. We are hesitant to accept a single explanation in terms of a direct temperature effect on photosynthesis, because on occasions changes in δ^{13} differences between the two trees would require up to 2 °C changes in the 5-yr averages of the temperature differences between sites 200 m apart. It is possible that the local canopy significantly influences the isotope ratio either by temperature effects of shading or by an isotope enrichment process as discussed by Keeling[16], with indirect temperature links. It is anticipated that information from a wider selection of trees, on both longer and shorter time scales, will resolve these questions.

The assistance of Dr D. Adamson of Macquarie University, who provided the dated timber, and Drs W. Budd, V. Morgan and Mr G. Wilson of the Australian Antarctic Division, who provided facilities and expertise for the mass spectrometry, is acknowledged.

Spontaneous measurement by young children

WHETHER or not the young child can make transitive inferences ($A>B,\ B>C\ \therefore\ A>C$) is still a controversial issue. Bryant and Trabasso[1] have claimed that he can, provided that he remembers the necessary information, but this claim has been disputed[2,3]. Youniss and Furth's main argument is that it is one thing to show that a child can make inferences, but quite another to demonstrate that he puts these inferences to any effect. They cite the measurement experiment of Piaget *et al.*[4] as evidence that the child does not make inferences spontaneously to solve problems. Here children had been shown a tower of bricks on a table and asked to build one as big on the floor. A stick the same height as the first tower was available. the question was whether the child would use this as a measure to equate the towers, thus making an inference ($A=B,\ B=C\ \therefore\ A=C$). Children below 8-yr old did not measure with the stick, and it was concluded that they had no idea of measurement. We here report experiments which lead to the opposite conclusion.

An alternative interpretation to Piaget's is that children do understand that it is possible to use intervening measures, but did not in this case realise that a direct comparison of the two towers by eye might be unreliable and thus that some measurement was needed. We decided to test this notion in three experiments in which, as the two quantities to be compared were invisible, it was very obvious that a direct comparison was not viable. We predicted that here children would measure.

Our experimental test involved 4 trials; in each the child was given two identical looking black wooden blocks (8 inch high, 3 inch wide) side by side on a table. Each had a hole in the top, the complete depth of which could not be seen: the hole was either 6 or 4 inch. In 2 of the 4 trials the holes were the same (6 inch with 6 inch, 4 inch with 4 inch): in the other two one hole was 6 inch, the other 4 inch

Between the two blocks lay a 10-inch long stick: its central 2-inch portion was yellow while the surrounding 4 inch at either end was red, so that the yellow portion was uncovered when placed in a 4-inch hole and covered in a 6-inch hole.

In each trial the child was asked to find out whether the two holes were the same and, if not, which was the deeper. We wanted to know if the child would spontaneously use the stick as a measure to make this comparison. If he did not on any trial he was given a prompt to use the stick as a measure.

In experiment 1, 20 5-yr olds and 20 6-yr olds were also told on each trial to use the stick though they were not told how. In experiment 2 the same number of 5 and 6-yr olds were told nothing about the stick. In experiment 3 the same number of 5 and 6-yr olds were given the same task as in experiment 2, except that the entrance to the two holes was widened and painted white, to see if this would distract the child from measuring. (The depth of the holes was still invisible.)

Also in each experiment each child was given a pre- and post-test version of Piaget *et al.*'s measurement task, which was exactly the same except that it was miniaturised, with a toy table and towers and sticks which were either 6 or 4 inch.

All the children failed both traditional tower measuring tests in all three experiments. Many of them were, however, successful in our hole measuring task. As Table 1 shows, the majority of children used the stick as a measure without any prompting, and most of their judgments were correct. A substantial number of children were never prompted and were correct on every trial. There were no significant differences between age groups or experiments. We conclude that young children do have an idea of measuring.

In experiment 4 we tested our idea that a crucial factor is whether or not a child realises that a direct comparison will be unreliable with 40 5-yr olds and 40 6-yr olds. Half had to compare holes in Perspex boxes. To make direct comparisons of the visible holes unlikely we changed the depth of the holes in this experiment to 6 and 5.5 inch and we placed the blocks on different tables in both conditions. Otherwise the procedure was the same as before.

The prediction was that Perspex boxes, by encouraging direct comparisons, would lead to less measurement. Although the results (Table 1) provide some partial support for this prediction, the difference was not significant. Many children still measured even in this experiment.

Whatever is the importance of the child's appreciation of the precariousness of direct comparisons, we have established contrary to all preceding evidence that young children can spontaneously use intervening measures. This result has some educational significance and since the measuring must have involved inferences it is strong support for the claim that young children make, and benefit from making, transitive inferences.

Territory size, breeding time and mating preference in the Arctic skua

THE Arctic skua is a polymorphic seabird with three phenotypes in plumage—pale, intermediate and dark. The dates during the breeding season when new pairs breed are related to the phenotypes of the males[1,2]: on average, dark males breed before intermediate males who breed before pale males. This effect is most pronounced when the male has no previous breeding experience[3]. These observations can be explained by assuming that females have mating preferences for the darker males[2,4]. Each breeding pair of Arctic skuas defends a territory: some defend their territories very strongly, attacking intruders viciously, others seldom attack In the red grouse, androgen levels have been shown to determine both aggression and mating success of males[5]. We show here that the size of a male's territory may either correlate with breeding time and mating preference through a common cause, or determine them both directly.

Since 1973 we have studied the colony of Arctic skuas on Fair Isle This study has included the accurate surveying of the positions of the nests of all pairs of birds in the colony We have mapped the nests on paper, drawn the lines connecting each nest with its adjacent nests and then the lines perpendicular to, and bisecting, each of the connecting lines. This divides the area of the colony into polygons, each enclosing a nest Parts of the colony are occupied by great skuas as well as Arctic skuas The great skuas' nests were also mapped, since great and Arctic skuas show interspecific territoriality. We consider the area of each polygon to be a measure of the size of the territory. When territories are sharply bounded in a dense colony, they naturally tend to become polygonal[6]. Only pairs with territories surrounded by others were included in the following statistical analysis. The full details of this method of mapping territories and the statistical analysis will be described in a subsequent paper.

In the data from those males who are mating with a new female and who have previous breeding experience, the hatching date is negatively correlated with territory size. The larger the territory, the earlier the breeding date. The correlation is very significant statistically (see Fig. 1: $r=-0\ 462$; $N=35$; $P<0.01$) There is no significant correlation if the males are without previous breeding experience ($r=-0\ 182$; $N=33$), and no correlation at all if they are breeding with the same female as in previous years ($r=0\ 015$; $N=100$). The overall correlation for males breeding with a new female, however, is very significant ($r=-0.334$; $N=68$), and the difference in the correlation for these males is not significant whether they have previous breeding experience or not ($\chi^2=1\ 544$).

Available evidence and casual observation at the colony suggest that the pairing of males with some previous experience of breeding may be different to the pairing of those with no experience. All the experienced males who changed their mate, bred on the same territory as they had done in previous years. Their new mate was often a female who had also bred nearby in the past. Immature males may find their mates differently, however. The immature birds return to the colony in the years before breeding, forming loose groups, or 'clubs', in particular parts of the colony. The inexperienced males probably select their mates from among the females of the club having taken over a territory during the year before breeding. Since the experienced males start the season with a territory, breeding time is a good measure of the time taken to find a mate. The inexperienced males, however, may have already paired with a female and defended a territory before breeding in the following year: if so, they would not form a group comparable to experienced males seeking a new mate, and breeding time would not be so closely related to territory size; the correlation is in fact reduced from −0.462 to −0.182, but, as we have already stated, this reduction is not significant given our present sample sizes.

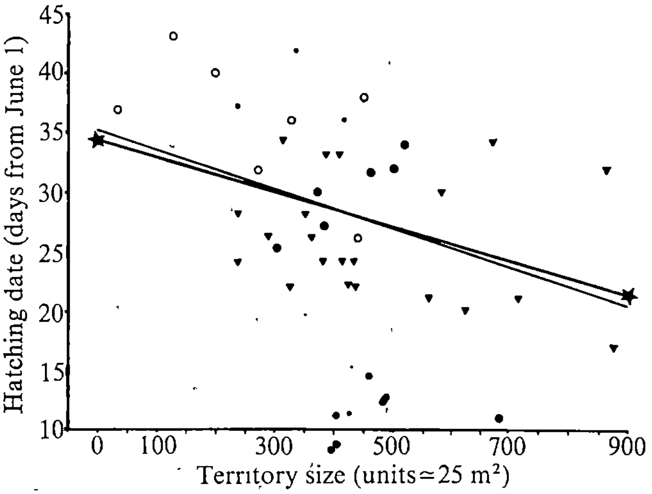

Fig. 1 Relationship between territory size and breeding time among males with previous breeding experience who are mating with a new female. A computer simulation, assuming that females have probabilities of mating proportional to the sizes of territories of males who are still unmated, gives the regression $y = 34.48 - 0\ 01455x$ (★—★) which is very close to the observed regression $y = 35.52 - 0.017x$ (———); ● Dark; ▼ intermediate; ○ pale

With the data available, we can only speculate on the cause of the correlation in the males between breeding time and territory size The following hypotheses would explain the observations:

(1) Females may simply prefer males with larger territories. We cannot see how this hypothesis can be tested.

Table 1 Fitting of parameters of negative assortative mating to the data of Murton *et al.* on matings between phenotypes of feral pigeons

Parameters fitted	Values of the fitted parameters at maximum likelihood	Values of χ^2	Degrees of freedom
None	—	50.869	6
α	0.340	40.945	5
β	0.508	26.856	5
γ	0.397	35.243	5
α β	0.327 0.520	8.271	4
α γ	0.355 0.416	10.782	4
β γ	0 508 0.376	6.565	4
α β γ	0 000 0.508 0 376	6.565	3

In the model, the females have preferences α, β and γ to mate with the phenotypes 'wild type', 'blue checker' and 'dark-blue checker'. The preferences are expressed only when the male's phenotype is different from the female's. Also included in the data were rare birds with other phenotypes. These were grouped together as 'others' and it was assumed there were no female preferences in their favour.

(2) Territory size may determine both breeding time and mating preference. Females will be more likely to land by random choice on the larger territories. The male with the larger territory will therefore pair earlier in the season. Such an effect would certainly account for the correlations we have observed. Given the data of Fig. 1, we have computed for each female the probabilities of mating proportional to the sizes of territories of males who are still unmated. This gives a correlation coefficient of -0.393 which is not significantly different from the observed correlation. Unfortunately this simple and satisfying hypothesis cannot be the complete explanation of our observations· as we have already said, when males change their mates,· the females usually come from nearby territories and not at random. Nonetheless, some of the females may be arriving to land on the territories at random, and if the darker males have larger territories this would partly account for their earlier average mating time and the mating preference in their favour. Sexual selection would thus favour increased territory size since earlier pairs have greater reproductive success.

(3) Territory size and breeding time may both be determined by a common cause. Territory size may be a measure of the intensity of breeding behaviour It would then be related to the mating preferences of females for the different phenotypes of males. O'Donald, Wedd and Davis[2] and O'Donald[4] estimated the mating preferences for intermediate and dark males according to a number of specific models of mating preference. The best estimates suggested that ~29% of females preferred intermediate males and 18% preferred dark males: these were the values that gave the closest fit by maximum likelihood. On Fair Isle, intermediates mate assortatively. A model of assortative mating gives an estimate of the mating preference for intermediates which agrees with that obtained from the distributions of breeding times[7,8]. The mating preference for dark males is only slight and not statistically significant, but this is perhaps to be expected in view of the small number of dark males in the sample. If the mating preferences are determined by sex drives of the males, we should expect that the intermediate and dark males would also have the larger territories; they do, but not significantly so, for our present sample contains only few pale males (see Fig 1). Our data are fully in agreement with the expectations of this hypothesis but to test it more rigorously further observations are required, both on territory size and its changes among pale, intermediate and dark males, and on the behaviour in the clubs of immature birds.

No correlation has been observed between territory size and breeding time in pairs that have bred together in previous years. There is also very little variance in the breeding dates of particular pairs in successive years[9]. The large territories tend, however, to get smaller and the small territories tend to get larger ($r=-0.698$; $N=21$; $P<0.001$) This could easily be explained if territories in successive years were random samples of available territories. Territories are not, however, allotted each year at random· the same pair always keep the same territory, whose size is not expected to vary since the average territory size in a particular part of the colony does not vary much from one year to the next. Perhaps larger territories take more defending since they are more likely to be disturbed by intruders. If the effort of defending a territory has evolved to an optimum by natural selection, a pair with a larger territory may, therefore, allow it to contract during the breeding season and so start with a smaller territory next year.

An interesting comparison between melanism in the Arctic skua and melanism in feral pigeons gives further support to our third hypothesis Murton, Westwood and Thearle[10] have shown that the melanic blue checker and dark-blue checker pigeons have larger testes during the breeding season and remain longer in breeding condition than wild-type pigeons. Pigeons show negative assortative mating of their phenotypes, however, unlike the positive assortative mating of the Arctic skua. We have analysed these data using a model of negative assortative mating. In the model, the females have preferences α, β and γ to mate with wild-type, blue checker and dark-blue checker males. These preferences are not expressed when the males have the same phenotypes as the females. (In the model of positive assortative mating for the Arctic skua[7], the mating preferences are expressed only when the males have the same phenotype as the females.) Table 1 shows the result of fitting our model to the data of Murton *et al* The females clearly prefer the melanic males. In pigeons, this is likely to have a physiological explanation since the larger testes of the melanics imply higher levels of gonadotropins and more intense sexual activity. It would be interesting to see if there are similar physiological differences between melanic and non-melanic Arctic skuas. Such differences would explain both mating preferences and the correlation between territory size and breeding time, but would not explain the assortative mating Positive assortative mating can evolve as a result of linkage disequilibrium between the genes for the preferences and those for the preferred phenotypes[11]. Negative assortative mating could evolve only as a result of some specific selective advantage.

Retrograde amnesia following electroconvulsive therapy

AMNESIC agents, such as electroconvulsive stimulation, can cause loss of memory for events that occurred before treatment[1]. Usually as the interval between learning and convulsive treatment is increased, the resulting retrograde amnesia is diminished[1–3]. This temporal gradient of retrograde amnesia can sometimes cover several years[4]. Clinical descriptions of the amnesic syndrome suggest that information about the temporal sequence of events can be more severely impaired than other aspects of memory[5,6]. Thus, an amnesic patient may describe a past event accurately but be unable to report when the event occurred. We have administered a new remote memory test based on former one-season television programmes to psychiatric patients receiving bilateral electroconvulsive therapy (ECT), and report here that memory for temporal order is markedly affected by ECT. ECT caused retrograde amnesia for order information about programmes broadcast from 1 to ~7 yr before treatment, but not for programmes broadcast from 8–17 yr before treatment.

The subjects were 17 female and 3 male psychiatric inpatients 27–64 yr old (mean=45 yr), for whom a course of bilateral ECT had been prescribed for relief of depressive

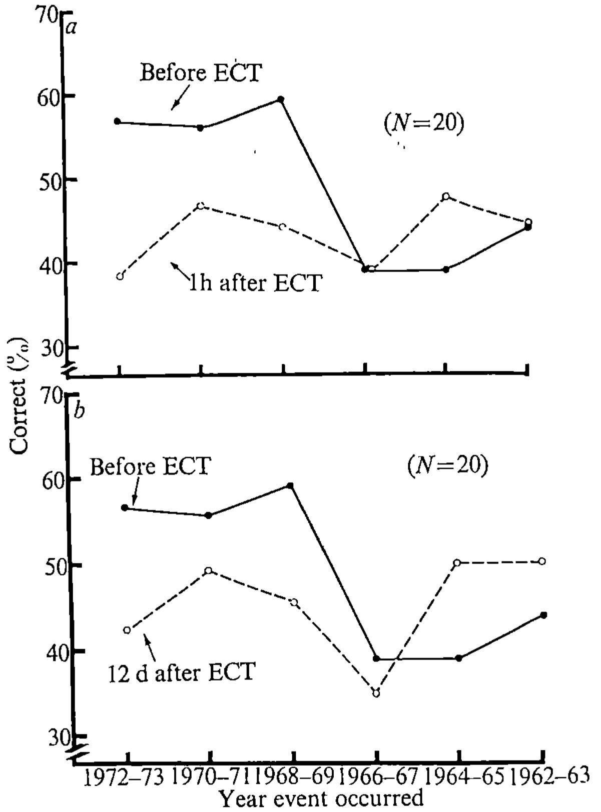

Fig. 1 Results of the test requiring temporal judgments about remote events administered to depressed psychiatric patients receiving a course of bilateral ECT. Testing was conducted before ECT, 1 h after the fifth treatment (*a*), and 1–3 weeks (mean = 12 d) after the completion of treatment (*b*). The test asked patients to select from sets of 3 former television programmes the one that was broadcast most recently. Comparisons were always between a programme broadcast for one season between 1962 and 1973 and two programmes broadcast for one season 5 years earlier. The time indicated is that when the correct choice was on the air. Values >42% are significantly above the chance level of 33% ($t>2.1$). ECT selectively impaired performance for the time period 1968–1973.

illness. Four of these 20 patients had received one course of ECT from 3 months to 14 yr previously. ECT was given with a Medcraft (B-24) machine (140–170 V, 0.5–1.0 s), with temporal–parietal electrode placement. This treatment was given three times per week on alternate days under barbiturate anaesthesia (methohexital sodium, 60–120 mg), and atropine (0.8 mg), with full muscular relaxation (succinylcholine, 20–60 mg).

The temporal judgment test was based on previously described recognition tests[7,8] involving the names of 85 one-season television programmes, 5 from each year 1957–1973. Popular exposure of the programmes from each year was relatively similar, and names were apparently learned close to the time the programmes were on the air. A three-alternative, multiple-choice test of 36 questions was constructed that repeated the question: "Which television programme was on the air most recently?" The correct answer was always the name of a programme that was broadcast for one season from 1962 to 1973. The two incorrect choices were the names of programmes broadcast 5 yr before the correct choice, 1957–68. The order of the 36 questions was random with respect to the periods they covered. All patients took this test 12–18 h before their first treatment, 1 h after their fifth treatment, and 6-25 d (mean = 12 d) after completion of their course of ECT (5–18 treatments, mean = 9.0). Testing was conducted from October 1974, to August 1975.

Figure 1 shows performance on the temporal judgment test before and after ECT. Before ECT, patients performed similarly to a control group[8] of 30 hospital volunteers ($F=0.1$, $P>0.3$). Apparently performance on this test was not noticeably affected by depressive illness. One hour after the fifth ECT (*a*), the performance was markedly impaired. The effect of ECT on 1968–73 scores accounted for 90% of the variance in before–after scores, and the before–after difference was significant for 1968–69 ($F=4.8$, $P<0.05$) and 1972–73 ($F=7.0$, $P<0.05$).

The results cannot easily be explained by gross confusion or by an inability to obtain high test scores after ECT. First, verbal IQ is normal by 1 h after 5 bilateral treatments[4,9]. Second, ECT did not simply reduce the frequency of high scores across all time periods. For the three periods not affected by ECT (1962–1967), patients obtained 15 scores of 67% or better before ECT and 14 scores of 67% or better after ECT. Thus, the impairment after ECT cannot be attributed to a global impairment in the ability to perform well, but is consistent with the interpretation that ECT selectively affected memories acquired in recent years. This conclusion is also supported by the fact that after ECT the score for 1972–73 was lower than the score for any other time period and was not significantly above the chance level of 33% ($t=0.9$, $P>0.3$).

Figure 1*b* shows that the impairment in temporal judgment for remote events persisted 1–3 weeks after completion of treatment. At this time the effect of ECT on 1968–1973 scores accounted for 71% of the variance in before–after scores, and the before–after difference was significant for 1968–69 and 1972–73 ($F>9.0$, $P<0.01$). A comparison of performance 1 h after the 5th ECT with performance 1–3 weeks after the completion of ECT indicated that no recovery had occurred during this period. The scores were nearly identical on these two occasions ($F=0.7$, $P>0.3$) and did not differ by >6% for any period.

These results indicate that ECT markedly disrupted the ability to make temporal judgments about remote events. Compared to amnesia for the names of former programmes[4], retrograde amnesia for temporal information about these programmes was more extensive and persisted for a longer time after treatment. Thus, amnesia for names of former programmes covered the past 1–3 yr, whereas amnesia for temporal information covered ~1–7 yr. Memory for the names of past programmes had recovered by 1–2 weeks after a course of ECT (mean = 7.6 treatments)[4], whereas judgment of temporal relationships between these programmes was still impaired 1–3 weeks after ECT (mean = 9.0 treatments). A long term follow-up study is now in progress to determine how long after ECT the disturbance of judgment remains.

Our results, together with previous experimental findings[4,10] and clinical case reports[11,12], support Ribot's hypothesis[13] that the resistance of memory to disruption increases with time. These results differ from findings that ECT[9] or Korsakoff psychosis[14] caused retrograde amnesia for past public events that affected all past time periods almost equally. Ageing also appears to affect memory for past public events equally across all time periods, rather than to cause a greater loss of memory for more recent time periods[15,16]. These studies do not, however, provide strong evidence for or against Ribot's hypothesis. First, the performance of Korsakoff patients[14] was so close to chance for questions about past time periods that a tendency for performance to be affected differently could easily have been masked. Indeed, in a subsequent study using easier questions, Korsakoff patients did exhibit a selective retrograde amnesia for more recent time periods[10]. Second, in the study of remote memory it is difficult to compare results for different times unless efforts are made to eliminate possible sources of sampling bias[15]. Third, performance of normal subjects was usually about the same for all times (1930–1969)[9,15], possibly because the absence of questions about the most recent years precluded the appearance of a forgetting curve. In contrast, normal performance on questions about former television programmes, including questions about the immediately preceding years, was much better for recent periods than for more remote periods[7,8]. One interesting possibility is that the development of resistance to amnesia parallels the course of normal forgetting. By this view, differential resistance to amnesia should not be demonstrable in the asymptotic limb of a forgetting curve.

Taken together, the evidence supports the conclusion that the resistance of memory can develop for several years after learning, and that temporal order information is particularly vulnerable to disruption. The neural substrate of memory may change over the years so that material in memory becomes both harder to recall and more resistant to disruption.

Development of visual stimulus-seeking in dark-reared kittens

EARLY visual experience is important for the development of vision in kittens. The response specificity of visual neurones for different environmental features can be affected by selective visual exposure to those features, and leads to long term changes in visual capacities[1–4]. Modification occurs only if the kitten is exposed selectively during the first three months of life. The peak period of sensitivity for "tuning" seems to occur between days 28 and 35, and thereafter declines rapidly; by the end of the second month, neuronal connections are less readily modifiable[5–6]. The peak of the sensitive period coincides with the clearance of the ocular media[7], the beginnings of adequate locomotor control (M. S. Levine, C. D. Hull, and N. A. Buckwald, unpublished), completion of the most active phase of myelination in the optic nerve and optic tract (C. L. Moore, R. E. Kalil, and W. A. Richards, unpublished), and the period of greatest synaptic density in the visual cortex[8]. In the present study we show that kittens do not spontaneously seek light at this time. Rather, there is a sudden onset of light-seeking behaviour at two months of age, when the cortical contour-coding system is not very sensitive to environmental modification, and many other adult visual characteristics have already been acquired.

Table 1 Pattern of self-induced exposure to visual stimulation in light- and dark-reared kittens

	Short presses (<0.5 s)		Long presses (≥9.5 s)

Light	0.498	0.289	0.043	0.167

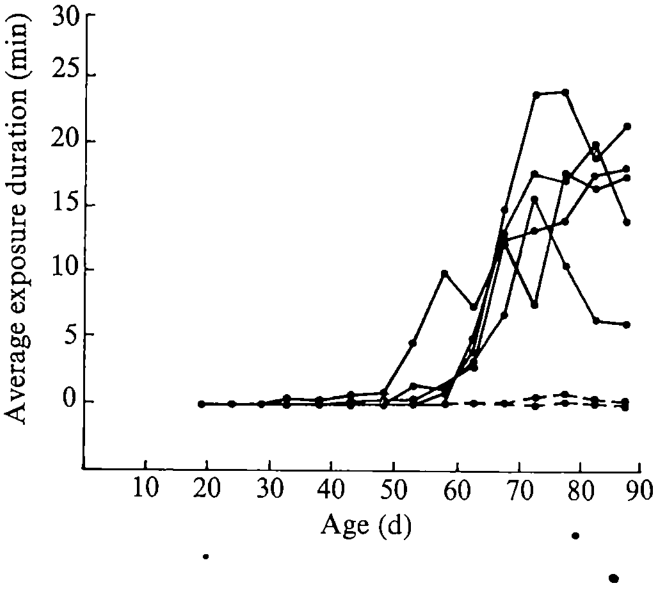
Proportion of short and very long presses within 10-d blocks before and after onset of light seeking.

Beginning at 5 d of age (before the eyes are open), six kittens taken from three litters were housed with their mothers in large nesting cages in a completely dark room where they remained for 3 months. From day 15 for 1 kitten, day 20 for 2 and day 23 for 3 kittens, to day 90, the kittens were transported in a light-tight box and placed individually each day in an experimental chamber, 76 cm wide by 91 cm long. A cylindrical tunnel, 6.5 cm in diameter and 34 cm long, extended from the rear of the chamber. A transparent Plexiglas panel, measuring 10×10 cm and recessed 5 cm, was positioned in the near end of the tunnel. A pattern of stripes subtending a visual angle of 15° was mounted at the far end of the tunnel and was illuminated continuously when the panel was pressed. Different cats were exposed to stripes of different spatial frequencies, but this did not seem to influence the pattern of responding. The tunnel was maintained at eye level by adjusting the level of the floor to compensate for the kitten's growth.

At the beginning of each session the kitten's nose was pressed against the panel several times for a total of about 5 s of stimulation. In addition, after the kitten had been left alone in the chamber, the light was flashed briefly to signal the position of the panel. Subsequently, the kitten could obtain light only by pressing the panel.

Two light-reared controls were treated identically except that they were housed in a larger cat colony maintained on an alternating 12 h light–dark schedule. One of the kittens reared in the dark served as an auditory control. It was allowed access to light only on alternate days. During the sessions every other

Fig. 1 Minutes of self-produced exposure per session, averaged over 5-d periods, expressed as a function of age of the kittens. Solid lines represent individual dark-reared subjects; broken lines, light-reared controls.



day, pressing the panel turned on a tone (maximal energy between 3,000 and 4,000 Hz) instead of the light.

Four of the dark-reared kittens and both light-reared kittens were given two 1-h sessions daily. The auditory control and one other dark-reared kitten were given two sessions per day until day 70 and thereafter were run only once per day.

Figure 1 shows minutes of self-produced exposure per session, averaged over 5-d periods, for all the animals except the auditory control. Neither dark- nor light-reared kittens press for much light in the first two months of life. Beginning at about day 60, however, the dark-reared kittens show a dramatic increase in self-produced exposure to light, in sharp contrast to the controls.

The increase in exposure is accompanied by a change in the pattern of responding. Both the number of presses and the average press duration increase. Before day 60, the typical mean press duration rarely exceeds 1.0 s (median rarely exceeds 0.5 s), but afterwards it seldom falls below 3.0 s (median between 1.0 and 4.0 s). Shorter presses and brief "knocks" become much less frequent, and some very long presses are produced. Before day 60, a press of 5 s or longer is rare, but afterwards presses of 1–3 min are not uncommon. Presses of up to 8 min were recorded on several occasions. Table 1 shows the shift in pattern of pressing for each group. Although there is a marked difference between groups, the pattern is consistent within each group.

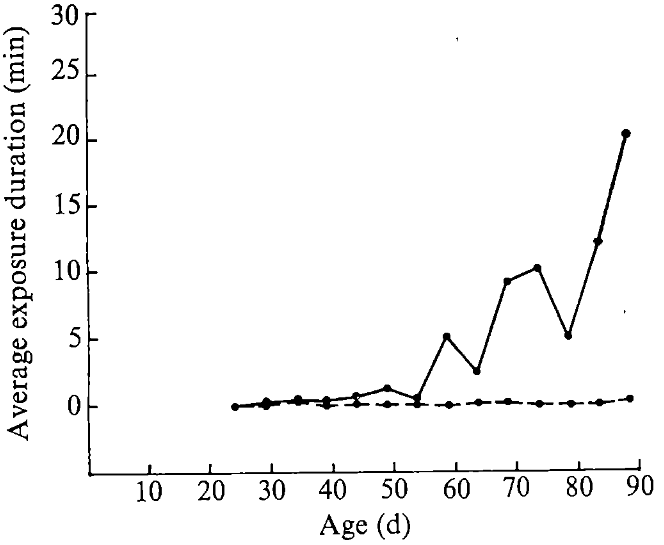


Fig. 2 Minutes of self-produced exposure to light (solid line) or sound (dotted line) per session, average over 5-d periods for one kitten.

All the dark-reared animals begin to change their behaviour at about the same age. Perhaps it could be argued that lack of strength or motor coordination prevents the kittens from panel pressing intensively before two months of age. Our data do not support this notion. All the kittens had pressed the panel for brief periods before day 30. There is no gradual increase in the number of seconds of exposure with time nor is any relationship between onset of the behaviour and body weight apparent.

It seems probable that the kittens were seeking visual stimulation specifically, rather than some general increase in sensory input. Figure 2 shows the data for the kitten allowed alternating access to light and sound. Clearly it does not seek the auditory stimulation. Typically, it would press for several seconds at the beginning of the session and then not press at all for the remainder. When light was available, it would press for prolonged periods. Additional control sessions were run for the other kittens in which, for alternate 15-min blocks within the 1-h session, pressing the panel did not illuminate the pattern. With no light contingency, the kittens quickly stopped responding, even though auditory stimulation was available from a microswitch which operated when the panel was pressed.

As was pointed out, the peak sensitivity for the "tuning" of cortical neurones seems to occur in about the fifth week of life[9–10]. Why should kittens not attempt to gain much access to light until cortical modifiability has declined? Perhaps they only seek such experience when the visual system is approaching a relatively stable stage, i.e., after the ocular media have cleared and the feature detectors have been tuned[6–8].

Our results do not throw light on the functional significance of the onset of light-seeking; the phenomenon does not seem to be related to the development of contour detecting mechanisms, rather it may point to other developmental processes in the visual system. Indeed it has been argued[11] that the main sites at which perceptual learning influences the system are probably not at the contour coding level.

There is a great temporal discrepancy between electrophysiological studies of cortical maturation, which place the peak sensitivity of the critical period at one month of age, and the present behavioural evidence, which demonstrates an abrupt, light-oriented behavioural change about a month later. The present results emphasise that the functional tuning of the contour-coding system of the visual cortex cannot simply be equated with the process of perceptual development.

Effect of constant light on nychthemeral variations in serum testosterone in male *Macaca radiata*

CIRCADIAN and seasonal variations in reproductive functions of mammals have been investigated extensively[1]. Serum testosterone exhibits a nychthemeral variation in man[2–6] and the rhesus monkey[7,8]. Exposure of laboratory rodents which are nocturnal in habit to continuous illumination causes precocious puberty in immature rats and hamsters[9], and constant oestrus in cycling rats due to elevated gonadotropins[10]. Conversely, prolonged exposure to darkness causes atrophy of testes in the hamster due to suppression of circulating FSH and LH[11,12]. Relatively less information is available on the effects of light on reproduction in the human and non-human primates. From a study of the effects of constant light on serum testosterone in the male bonnet monkey (*Macaca radiata*), we have found that *M. radiata* shows a nychthemeral variation in serum testosterone.

Adult male monkeys weighing 8–10 kg were lodged in individual cages in rooms measuring 10×10×8 feet in our primate facility. Artificial cool white light was provided by installing two fluorescent tube lights (40 W, 250 V) at a height of 10 feet. The rooms were not air-conditioned but were provided with a powerful exhaust fan to maintain good air circulation. Normally, lights are kept on in these rooms between 0600 and 1800 (IST). The animals were kept under this light–dark (LD) schedule of 12 : 12 h for 3 months before being used for experiments. The monkeys were fed pelleted food (Hindustan Lever Monkey food) and vegetables three times a day, water being available at all times.

Blood was withdrawn by venepucture at 6-h intervals. The monkeys were not anaesthetised during these operations. Testosterone in the serum was estimated by radioimmunoassay according to standardised procedures (see footnote for Table 1 for details).

The results show that *M. radiata* like the rhesus monkey (*M. mullata*) also exhibits a nychthemeral variation in the secretion of serum testosterone with a 6–12-fold increase during the night hours (Table 1). Exposure to constant light for 72 h did not bring about significant change in this pattern. Exposure to continuous illumination for 4 weeks, however, abolished the nocturnal surge, this being restored once the lighting was shifted back to normal schedule of LD 12 : 12 (Fig. 1) While restoration to normality seems to be a relatively fast process, a minimum of 15 d of continuous illumination was found necessary to abolish the nocturnal elevation of serum testosterone. In two of the monkeys, although there was a reduction in testosterone levels at 2000 due to constant light, the levels at 0800 and 1400 increased over the control by two- to threefold. The reason for the latter is at present not clear to us.

While in the rhesus monkey no elevation in LH levels have been observed that can be correlated with the nocturnal rise of testosterone[8], in the human Judd *et al*[5] observed that the pulsatile rise of testosterone during the nocturnal period is closely preceded by pulsatile changes in LH levels. But since other workers[13,14] have not observed a change in amplitude and frequency in LH peaks between day and night hours, they suggest that the nocturnal rise of testosterone may be related to a variability of Leydig cell sensitivity to LH during these hours[5].

Table 1 Nychthemeral variations in serum testosterone in male *Macaca radiata*

Time of day	Testosterone equivalent ng per ml serum Mean ± s.e.m. ($n = 7$)
0200	26.0 ± 3.90
0800	3.96 ± 0.69
1400	2.29 ± 0.26
2000	25.6 ± 3.72

The procedure adopted for extraction of steroid from serum and radioimmunoassay was essentially similar to that described by us earlier for progesterone[17]. 2,4,6,7,-^{3}H-testosterone was used as the label and the antiserum used was prepared to testosterone-3-oxime–bovine serum albumin. The antiserum at the dilution used (1 : 40,000 final dilution) cross reacts significantly only with dihydrotestosterone to an extent of 66.0%. The specificity of the antiserum is adequate for the present study, as the latter aims at measuring the total testosterone equivalents.

The nocturnal elevation of testosterone appears from our study not to be influenced by the presence or absence of females in the vicinity, as the males in the present experiment were housed separately from the females. It should, however, be mentioned that the males in the breeding units exhibited a much higher nocturnal level of testosterone (approximately 1.5–2-fold) than the males used in the present experiment.

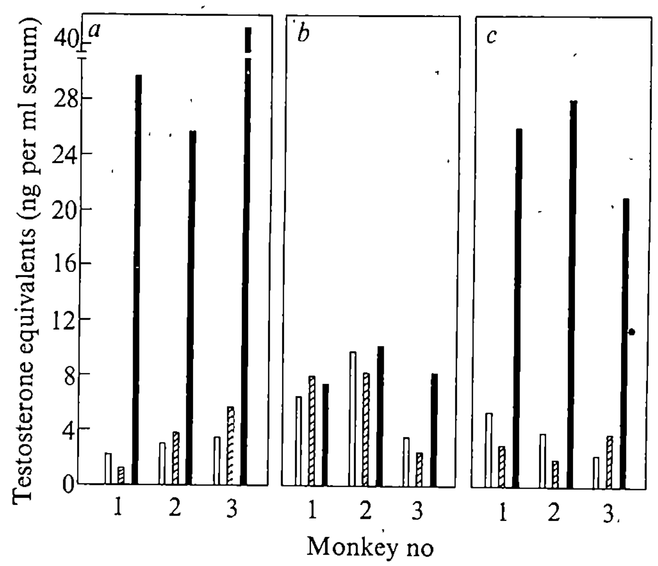

Fig. 1 Effect of continuous illumination on serum testosterone in male bonnet monkeys. Three of the monkeys which showed typical nychthemeral pattern as in Table 1 were selected for this study. *a*, LD, 12 : 12; *b*, LD, 24 : 0; *c*, LD, 12 : 12. Open columns, 0800; hatched columns, 1400; black columns, 2000.

The abolition of nocturnal surge of testosterone in monkeys under constant illumination could be due to either a suppression of gonadotropin secretion or loss of responsiveness of the testis to unchanged levels of gonadotropins.

Interestingly, the monkey differs from the rat in that constant light brings about an increase in pineal hydroxy indole O-methyl transferase (HIOMT) activity resulting in an elevation in melatonin levels[15]. Since it is known that many pineal substances (for example, melatonin) are antigonadotropic in nature, it is possible that an increase of these factors in monkeys under constant light might be responsible for inhibiting testicular function. The observation that blindness in humans is associated with early gonadal maturation[16] lends support to our suggestion. It should, however, be pointed out that as constant light is a stress, a direct action of the factors associated with this stress on the testis cannot be ruled out. All the same it should be mentioned that no change in the time of sleeping was observed when the monkeys were kept under constant light.

In conclusion, the present study shows that the bonnet monkey exhibits a high level of serum testosterone during night hours, which is abolished on exposure to constant light, suggesting that this variation in serum testosterone is a nychthemeral rhythm.

We thank the Indian National Science Academy, New Delhi for financial support. The antiserum to testosterone used in this study was a gift from Dr D. K. Mahajan, The M. S. Hershy Medical Centre, Pennsylvania.

Timing of the photoperiod and the hour of birth in rats

THE factors determining the onset of labour are largely unknown, though the regulating mechanisms seem to originate from both the foetus and the mother. The foetus seems to determine the day of birth, through the maturation of the pituitary–adrenal–placental axis, but the mother may provide a fine control, determining the precise hour of birth. Labour varies greatly in its timing and speed of execution, presumably as the result of selection to ensure the maximum probability of survival of both the mother and offspring. Environmental factors such as light, tides and predators are of great importance, providing cues which influence the final hour of birth. Even women, who during childbirth are confined in a most artificial environment, show a marked tendency to deliver in the early hours of the morning[1–4].

The reproductive functions of the laboratory rat are linked to the diurnal changes in light and darkness. When subjected to an artificial photoperiod with light from 0500 to 1900, rats of most strains release their ovulatory surge of luteinising hormone from about 1500 on the day of pro-oestrus, and then ovulate between 0200 and 0400 the next morning[5]. Similarly, at the end of pregnancy, a complex series of changes in the plasma levels of various reproductive hormones[6–12] prepares the animal for labour. As the secretion of these hormones is under hypothalamic control, it may reasonably be asked whether the timing of labour is linked to the photoperiod. The rat gives birth between days 22 and 24 of pregnancy (day 1 = sperm-positive vaginal smear), though reliable data, where all extraneous factors have been excluded, are limited Boer *et al.*[13] recorded by continuous observation an abrupt increase in the incidence of labour at about 1200 on day 22, with a second and much smaller peak during the early hours of day 23. This study involved some, albeit slight, disturbance of the animals, but the rapid onset of births and their bimodal distribution suggested the existence of an accurate timing mechanism. In the results reported here, we have sought to control the various extraneous parameters which might influence labour, to provide reliable information on the hour of normal delivery. We have also investigated the degree to which the time of delivery is determined photoperiodically

The hour of birth was recorded in 446 rats of a Wistar strain (laboratory bred from MRC Porton stock); 296 were primiparous, weighing 240±27 g (s d) at the time of mating; 87 were multiparous, weighing 268±27 g; and the remainder were of unknown parity Groups of 80–120 pro-oestrous rats were caged singly with a male from 1600. The following morning, the males were removed and mating confirmed in about 80% of the females by the presence of copulation plugs on the dropping trays or sperm in the vaginal smear. These animals were transferred to single cages until delivery occurred some 22–23 d later. All other stock were removed from the delivery room and the doors were locked. Sufficient food and water were provided so that replenishment was required only once during pregnancy. An artificial photoperiod of 14 h light : 10 h darkness was provided for the controls and experimental groups until day 12, with the lights on from 0500 to 1900 each day. On day 12 only, the various experimental groups were subjected to a longer or shorter day by the retardation or advancement of the onset of darkness. Thereafter, the ratio of light to darkness remained at 14 : 10; so the rats had effectively been transferred to a new "time zone". The onset of labour was determined by observation every 3 h from 0500 on day 21, the red light of a torch was used during the hours of darkness. This frequency of observation was chosen as a compromise between the need for accurate timing and the need to avoid disturbance. The timing of birth was scored as that 3-h interval within which the first pup was delivered. All dams with litters were removed from the experimental room 6 h after delivery.

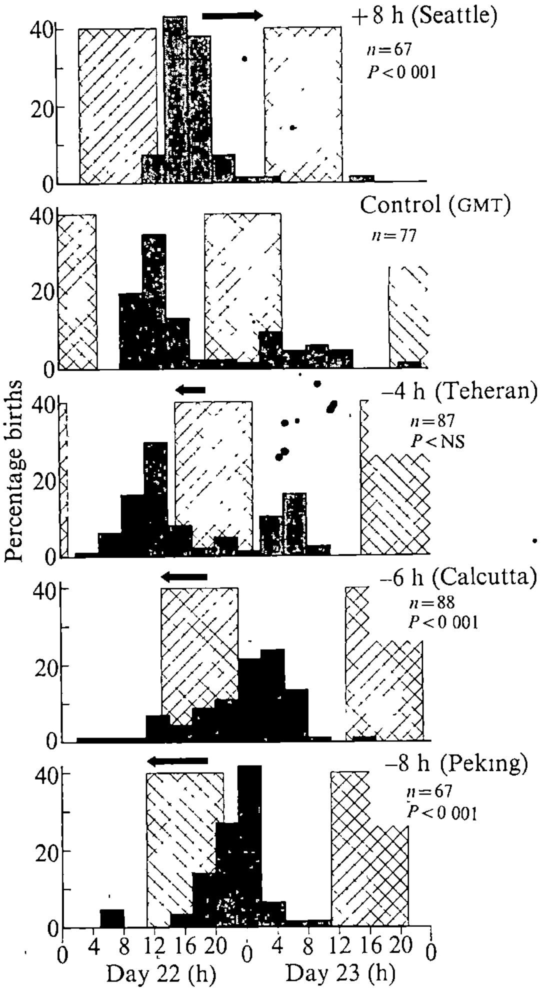

Fig. 1 Effect of the timing of the photoperiod on the hour of birth in rats. The periods of darkness on days 22 and 23 are shown by the hatched areas. The control photoperiod, and the photoperiod of all experimental treatments up to day 12, consisted of 10 h of darkness from 1900 and 14 h of light. Day 12 was lengthened or shortened and the adjusted photoperiod maintained for the rest of pregnancy. The approximate time zones to which, effectively, the rats were transferred are given by reference to the place names. All distributions differ significantly from each other (with the exception of the control (GMT) and −4-h (Teheran) comparison), when compared by either a Kolmogorov–Smirnov or a grouped χ^2 analysis ($P\ll0.001$)

The distribution of deliveries in the control group of 77 rats was bimodal, with mean and median time values of 1619 and 1313 (day 22), respectively (Fig. 1). This pattern of deliveries was very similar to that obtained by Boer *et al.*[13], although the distribution was advanced by about 3 h in all respects. The photoperiod could have been responsible for this time difference, because the animals in Holland[13] were given 12 h of light from 0700 to 1900, but differences due to rat strain and environmental factors cannot be excluded. A further group of animals ($n=55$) was treated identically to the control group except that it was subjected to continuous darkness from the morning of day 21. The timing of labour was almost unchanged; it was again bimodal with mean and median values of 1519 and 1226, respectively. These times were slightly earlier than those of the controls, but the differences were not significant.

Four groups of rats were subjected to time-zone changes in mid-pregnancy; the results are shown in Fig. 1. The lengthening of day 12 by 8 h (the equivalent of transporting the rats from London to Seattle) delayed the time of expected delivery and created a single distribution with mean and median values of 1710 and 1654 respectively. The reduction of day 12 by 4 h (Teheran time) slightly advanced the onset of the distribution (one animal gave birth before 0500). The second peak on day 23 was more accentuated than in the controls, but the overall difference remained non-significant. The reduction of day 12 by both 6 and 8 h (to Calcutta and Peking time) caused profound changes in the distribution. After the 6-h time shift, the mean and median times for delivery were 2322 and 0044 (day 23); whereas, with the 8-h shift, the mean and median values were 2211 and 2306, respectively. Thus the median time of delivery changed by more than 11 h when day 12 was shortened from -4 to -6 h. Delivery seemed to be transferred from the light period of day 22 to the light period of the next day.

The parity of the mother did not influence the hour of birth. The mean litter size was 10.98±2.68 pups (s.d.) for primiparous rats and 10 92±2.78 for multiparous stock, and there was no correlation between the litter size and the hour of birth when the litters contained six or more young (maximum 17). The mortality rate was 4 2% overall, estimated from the number of dead pups 6 h after delivery, but the true figure was probably slightly higher, as some young may have been eaten without trace. Mortality rose to 39% for deliveries after 1100 on day 23, but most of these births were associated with dystocia. Thus the 12 litters that were produced after 1100 were excluded from the calculations of mean and median delivery times.

These results provide clear evidence that the onset of labour in the rat is determined, in part, by the animal's experience of the timing of the photoperiod in the days which precede labour. As in the study of Mitchell and Yochim[14], rats in the present series exhibited a preference to deliver during the hours of light. In spite of the shifting of darkness through the peak of the control distribution, the rats adjusted their time of delivery such that 82% of all births occurred during the 14 h of light Although Svorad and Sáchová[15] claimed that the tendency for the mouse to deliver in darkness could likewise be demonstrated by altering the light regime after mating, Porter[16] found that alterations in the timing of the photoperiod had no effect on the distribution of deliveries, so that mice delivered in light as well as darkness depending on a fixed copulation–delivery interval

In the present experiments, the provision of light *per se* was of no immediate significance, for when the animals were subjected to continuous darkness on the last day the distribution of the deliveries was not retarded; in fact, it was slightly advanced This suggests that it is the biological rhythm of the animal, rather than a cue from the onset of light or darkness on day 21–22, which determines the hour of birth As is known for other biological systems[17], these rhythms take several days to reset when animals are transferred from one time schedule of light and darkness to another, and are not immediately destroyed by the removal of one photoperiodic cue. The daily period of darkness seems to be associated with a physiological change which is inhibitory to labour, but a critical examination of Fig. 1 indicates that this inhibitory effect began to be expressed, as far as deliveries are concerned, 2–3 h before the onset of darkness and it terminated before the lights came on again. Fuchs[18] and Fuchs and Poblete[19] have reported that labour in the rat is presaged by an increase in uterine activity some two or more hours before birth. It is possible therefore that an inhibitory effect on delivery would be influencing maternal physiology 4–6 h before the onset of darkness.

The limits within which normal labour was observed to begin ranged from about 0500 on day 22 to 1100 on day 23, and within this range the median time of delivery varied by up to 12 h according to the timing of the photoperiod. Thus the onset of labour under control lighting occurs relatively early within the normal range, and no photoperiodic change investigated in this study substantially advanced the occurrence of labour The tail of the control distribution, with its second peak on day 23, seems to be a photoperiodic function, that is, some animals are prevented from delivering on day 22 by the impending onset of darkness at 1900 The advancement of day 12 by 8 h may provide a more satisfactory schedule for some experiments, since this resulted in a single statistically normal distribution, with 82% of the animals giving birth between 1400 and 2000 on day 22.

These results raise the important question of whether the endocrinological changes such as the decline in progesterone titres, the increase in oestradiol and prolactin levels, and the augmented output of prostaglandins, all of which are considered to be involved in preparing the uterus for labour, are retarded or advanced by alterations in the photoperiod These changes may, however, proceed on an independent time course, so that the precise timing of labour is determined by the arrival or removal of another and as yet undetermined photoperiod-dependent signal, which permits the activation of the already prepared uterus. Experiments are in progress to examine this question.

Deleterious effect of an anaesthetic on cultured mammalian embryos

THE teratogenic effect of certain tranquillisers on human and animal pregnancies has been known for many years[1–3]. Anaesthetics and other central nervous system depressants may also be teratogenic when given during early pregnancy, possibly because of the inhibitory action of these agents on mitosis[4]. Anaesthetics can also activate unfertilised mouse eggs *in vivo,* inducing them to develop parthenogenetically[5,6]. Chronic exposure to low levels of anaesthetics may result in a significant increase in spontaneous abortions and the birth of children with congenital abnormalities[7,8]. Experiments with rodents[9] which seemed to demonstrate that chronic exposure to anaesthetics could be teratogenic in early pregnancy have proved difficult to repeat[10], so that doubt has now been cast on the validity of these earlier results. Attention has also been drawn to the possible risk to the human foetus of surgery carried out during pregnancy[11]. In the experiments reported here we have demonstrated a direct, deleterious effect on early postimplantation rat embryos in culture of a single exposure to different doses of an anaesthetic.

Headfold-stage rat embryos of the CFHB strain were explanted during the afternoon of day 10 of gestation (day of finding sperm in the vagina=day 1 of pregnancy), and cultured *in vitro* for 24 or 48 h in heat-inactivated (56 °C, 30 min) homologous IC serum[12], prepared from blood withdrawn from the aorta of rats anaesthetised with ether. During heat inactivation the bottle containing the serum was opened twice to drive off as much ether as possible. Serum from the same batch was used for both control and experimental culture groups, with Avertin (Winthrop) added to the experimental groups. Except where shown in Table 1, the medium was equilibrated with a gas mixture containing 5% O_2, 5% CO_2 and 90% N_2 for the first 24 h and 5% CO_2 in air for the rest of the culture period. These conditions give optimum development *in vitro* for embryos explanted at the headfold stage (D. A. T. New, personal communication). Since the purpose of the cultures was to test the teratogenic effect of a specific anaesthetic agent, the pregnant females were not killed by etherisation but by cervical dislocation. Where embryos from more than one female were used in one experiment, these were divided equally between control and experimental groups.

In preliminary studies the embryos were cultured in watchglasses or 60-ml roller bottles by New's technique[13]. With this equipment the gas phase is considerably greater in volume than the volume of the medium. In this instance no teratogenic effect was obtained even with twice the standard anaesthetic dose of Avertin. In subsequent cultures, sealed embryological watchglasses or 12×75 mm plastic test tubes (Falcon, 2003) containing 3 ml and 5 ml of medium, respectively, were used, such that the volume occupied by the gas phase was less than 0.1 ml and 0.5 ml, respectively.

The standard dose of Avertin used to anaesthetise intact rats was used, where 1 ml of culture medium was assumed to be equivalent to 1 g body weight of an intact rat. The standard dose of Avertin used was 0.02 ml of a freshly prepared 1.2% solution of Avertin dissolved in 0.9% saline per ml of serum (or g body weight of an intact rat), equivalent to approximately 240 p.p.m. (by volume). Further groups of embryos were cultured for 24 h in serum containing twice, four times or six times the standard dose of Avertin. Some of these embryos were examined histologically, while others were transferred with the medium to a 60-ml roller bottle containing 2–4 ml of fresh anaesthetic-free serum and cultured for a further 24 h. At the end of culture, at 24 h or 48 h, embryos were examined under a dissecting microscope and an assessment of development was made using purely morphological criteria, such as the presence or absence of a beating heart, closure of the neural tube, the adoption of the foetal position ('turning'), somite number and the yolk sac diameter. Embryos which were not examined histologically were dissected free from embryonic membranes and their protein content was determined microspectrophotometrically[14].

When embryos were cultured with a large gas phase, there was no difference between controls and those cultured in once or twice the standard anaesthetic dose of Avertin for periods ranging from 10 min to 24 h (the results of this and subsequent cultures are presented in Table 1). When the volume of the gas phase was reduced, embryos grown for 24 h in twice the standard anaesthetic dose clearly developed less well (somites indistinguishable, less embryos with a heartbeat) than controls, and four and six times the standard anaesthetic dose had an even greater effect. When the culture period was extended to 48 h and the protein content of the embryos was estimated, there was a significant difference ($P<0.0025$) between control embryos and those cultured in twice the standard dose of Avertin.

The reduction in volume of the gas phase also resulted in a significant difference ($P<0.0025$) in protein content between control embryos and those grown in the standard

Table 1 Effects on early postimplantation rat embryos of a single exposure to different doses of Avertin

Dose of Avertin (multiples of standard dose)	Exposure to Avertin (h)	Total culture time (h)	Culture conditions	Total no of embryos	Protein content of embryo (μg) mean ± s.e.	Mean yolk sac diameter (mm)	Heartbeat		Average somite no	Neural folds		Turning

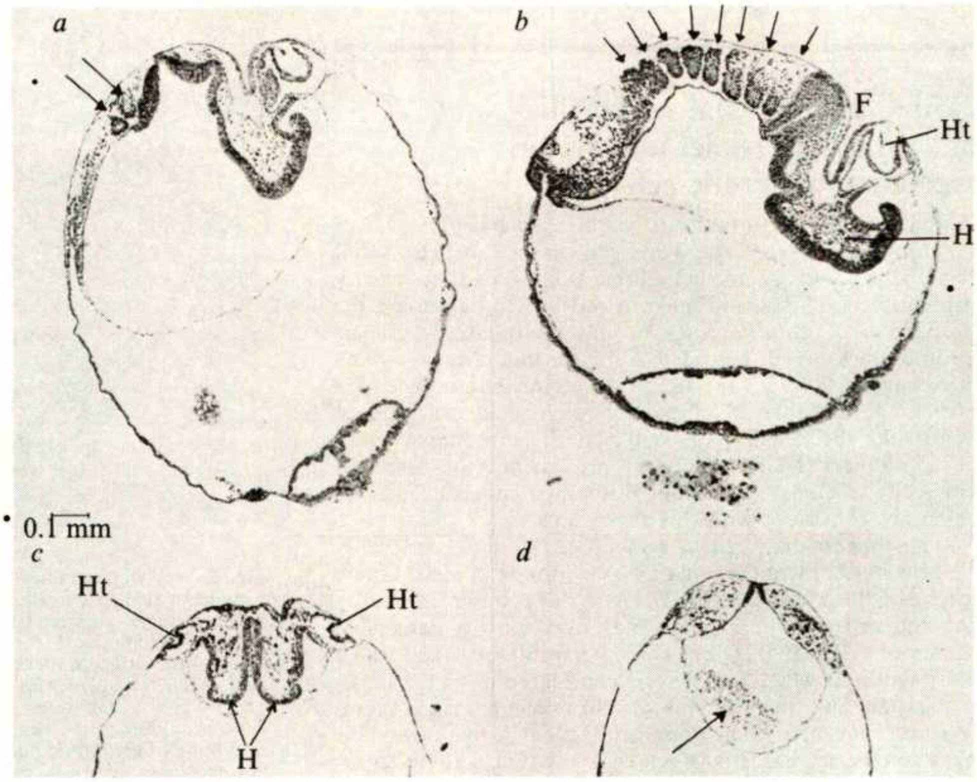

Fig. 1 *a*, Near sagittal section of conceptus cultured for 24 h in twice the standard dose of Avertin. Two poorly formed somites can be seen (arrowed). *b*, Sagittal section of control conceptus cultured for 24 h. Note the larger number of well formed somites (arrowed) compared with (*a*). *c* and *d*, Frontal sections of conceptuses cultured for 24 h in twice the standard dose of Avertin. The unfused heart primordia on either side of the head is shown in (*c*), and the cellular debris (arrowed) found in the amniotic cavity of experimental embryos is shown in (*d*). The scale is same for all figures: bar represents 0.1 mm; F, foregut; H, head; Ht, heart.

dose of Avertin. As in twice the standard dose, all embryos cultured for 48 h developed a heartbeat and closure of the neural folds was unaffected. The frequency of embryos which had 'turned', however, was decreased in the standard dose and twice the standard dose of Avertin compared with the controls. Differentiation, assessed by somite number, was unaffected by the standard dose, but was greatly retarded in twice the standard dose.

Histological examination of control embryos and those cultured in twice the standard dose of Avertin confirmed the detrimental effect of the anaesthetic on differentiation. In the experimental embryos the somites were poorly differentiated and fewer in number (Fig. 1*a*) compared with control embryos (Fig. 1*b*). As well as this effect on the paraxial mesoderm the heart seemed to be affected (Fig. 1*c*). In four out of seven embryos cultured in twice the standard dose of Avertin, cell debris was present in the amniotic cavity (Fig. 1*d*). This was also found when embryos were cultured in four and six times the standard dose. In the latter group the embryonic material consisted almost entirely of dead or dying cells. Debris was not found in the amniotic cavity of control embryos.

These experiments have demonstrated that the anaesthetic Avertin can be teratogenic in the rat, and that the degree of embryotoxicity is dose dependent. When a range of parameters of development was examined, rat embryos which had been cultured in serum containing Avertin were retarded compared with controls. It is not clear whether the type of growth retardation which was observed in apparently normally differentiating embryos as a result of treatment with standard dose of Avertin could be corrected by compensatory growth later in gestation[13].

The main advantage of the model used here over, for example, cell lines in tissue culture as a teratological test system, is that the use of whole embryos more closely resembles the situation *in vivo*. There is, however, the important difference that all the observations reported here result from the direct effect of known doses of Avertin on the embryo, independent of secondary maternal factors such as placental permeability. Further, the anaesthetic is metabolised *in vivo*, and the metabolic products may be more or less teratogenic than the original agent.

In view of these positive results, the factors which remain to be examined include the establishment of the minimal teratogenic dose and exposure duration of a range of anaesthetics. Experiments should also be carried out with embryos of different gestational ages, and different species. It would also be interesting to compare the sensitiveness of our experimental model with other models now in use for teratological testing.

It seems likely that anaesthetics other than Avertin may be teratogenic in species other than the rat. It would therefore be of clinical importance to determine whether any of the anaesthetic agents commonly used in human practice have a similar embryotoxic action when administered during early pregnancy.

We thank Dr D. A. T. New for advice and discussion, and Mrs S. M. Jackson for technical assistance. This work was supported by a grant from the Ford Foundation. C.E.S. is supported by an MRC grant to Dr G. M. Morris.

Partial chromosomal set labelling induced by ultraviolet microbeam irradiation of mitotic cells

It would be useful to find out whether a particular part of the chromosome set in the living cell can be labelled so that the labelled and unlabelled chromosomes can be clearly distinguished. This would make it possible to determine the localisation of chromosomes during interphase when the chromosomes are dispersed as tangled thin threads which cannot be traced with the light or electron microscope. We have suggested[1] that an ultraviolet microbeam can be used to provoke the labelling of part of a chromosome set with ^{3}H-thymidine (^{3}H-TdR). Here we present data on mammalian cell labelling following ultraviolet microirradiation which are consistent with this suggestion.

When mammalian cells are incubated with ^{3}H-TdR only the cells normally undergoing DNA synthesis (S phase) show uptake of the tracer into the DNA. After ultraviolet irradiation the cells not in S phase may also show a detectable uptake of ^{3}H-TdR (ref. 2). This is a result of unscheduled DNA synthesis which is generally considered to be the result of excision and replacement of ultraviolet-damaged bases by repair enzymes[3]. The unscheduled DNA synthesis also takes place after a partial nuclear irradiation with an ultraviolet microbeam. Ultraviolet microirradiation produces an alteration in an irradiated volume of nucleoplasm without apparently affecting the remainder of the nucleus or the surrounding cytoplasm[4]. It was found that ultraviolet microirradiation of the nucleus of HeLa or KB cells not in S phase produced a localised ^{3}H-TdR incorporation only over the zone actually irradiated by ultraviolet light[4–6]. Such observations of partial nuclear labelling have been obtained in experiments with interphase cells. During mitosis the chromosomes condense into clearly defined thick strands and the microbeam can be focused on to a distinct part of the chromosome set or even to a small region of one chromosome[7]. We have proposed that DNA of the microirradiated mitotic chromosomes can also be selectively labelled with ^{3}H-TdR and the postmitotic localisation of the labelled DNA can be determined by autoradiography.

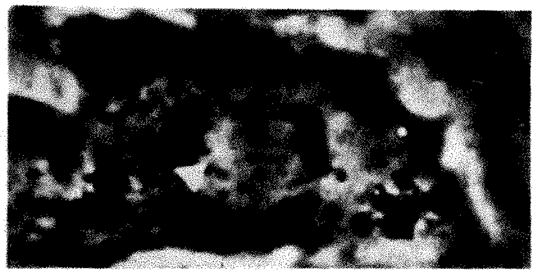

Fig. 1 Typical anaphase SPEV cell during ultraviolet microirradiation. The light triangle over the left chromosomal group indicates the area of irradiation (exposure 5 s at a dose rate of ~2×10^{-3} erg μm^{-2} s^{-1}). Phase contrast ×1,500.

The experiments were carried out on pig embryo kidney cells (SPEV) routinely maintained in medium 199 supplemented with 10% foetal calf serum. The cells were used 24 h after they were seeded in monolayer on a quartz coverslip mounted in a window of a sterile culture chamber. These cells were chosen because they remain relatively flat during the mitotic process, thus making the chromosome set easy to irradiate. The cells were irradiated through the coverslip by an inverted monochromatic (280 nm) ultraviolet microbeam with the spot area about 4 μm^2. A suitable dose was determined empirically by varying the time of irradiation. During metaphase or anaphase 20–25% of the chromosome set of each cell was irradiated. The chromosomal target was always located near the edge of the metaphase plate or within one group of anaphase chromosomes. The pattern of the anaphase cell irradiation is shown in Fig. 1. After irradiation of the anaphase cell only one of the daughter cells obtained a portion of irradiated chromosomes, but the other one could be used as a control. Incorporation of ^{3}H-TdR into postmitotic nuclei was studied by autoradiography.

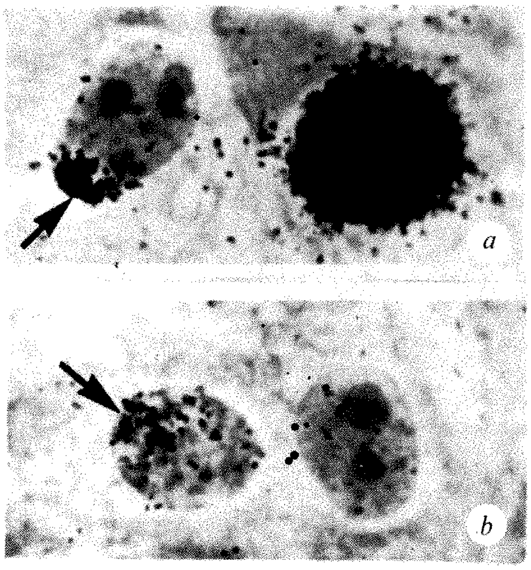

Fig. 2 Autoradiographs of interphase SPEV cells. The cells were incubated in culture medium containing ^{3}H-TdR (10 μCi ml^{-1}). Incubations were carried out for 1.5 h immediately after partial irradiations of anaphase chromosomes. The cells were then rinsed with culture medium and fixed in 3:1 ethanol–acetic acid. After treatment with 3% perchloric acid, autoradiographs using M emulsion were prepared and developed after 10 d exposure. Preparations were stained with haematoxylin. *a* and *b* (left hand), Postmitotic nuclei containing a portion of irradiated chromosomes. Arrows indicate the "patches" of unscheduled ^{3}H-TdR labelling. *a* (right hand), Non-irradiated nucleus in normal S phase. *b* (right hand), Unlabelled control nucleus not in S phase, ×1,500.

Fifty-six irradiated cells were studied. Within 1.5–2 h of irradiation these cells had completed cell division and formed daughter nuclei with decondensed chromosomes. These nuclei contained apparently normal interphase nucleoli, but sometimes they also included some prenucleolar bodies. The appearance of these bodies may be due to nucleolar organiser damage by ultraviolet microirradiation[8,9].

Autoradiography showed that partial ultraviolet irradiation of the mitotic chromosomes provoked unscheduled DNA synthesis in all cases. This synthesis can be clearly detected in the daughter nuclei as patches of unscheduled incorporation of ^{3}H-TdR. These labelled patches are presented in Fig. 2*a* and *b*. The label was never seen in the nuclei of the control daughter cells, since all these cells were not in S phase. The average grain number in the labelled patches (28 grains) was about 20 times greater than that in control nuclei. In the 22 nuclei studied the labelled patches occupied no more than 30% of the nucleus area (Fig. 2*a*). The remaining 34 nuclei exhibited incorporation of ^{3}H-TdR in 30–50% of the nucleus area (as shown in Fig. 2*b*). It is extremely likely that these patches of labelling are situated over the sites of the postmitotic localisation of the irradiated chromosomes.

Our results provide the first demonstration of localised DNA synthesis in interphase nuclei following ultraviolet microirradiation of mitotic chromosomes. Further studies are in progress with the aim of using this technique in an attempt to elucidate the localisation of different parts of the chromosome set during interphase. These studies should take into account the possible influence of irradiation on the postmitotic arrangement of chromosomes. Further experiments should, however, be carried out on cells with chromosomes which are few in number and large in size.

Mutation frequency at a recessive locus in haploid and diploid strains of a slime mould

IT is puzzling that mutants are isolated at a similar frequency in tissue cultures of haploid and diploid strains[1–3], for twice as many mutations have often been assumed necessary to produce a mutant diploid as to produce a mutant haploid. Explanations for the apparent high frequency of mutation in diploids[1–6] include epigenetic effects[1–3], changes in gene dose[7], dominant mutations[8], recessive X-linked mutations[4] and heterozygosity before selection[9]. Most recessive autosomal mutants are assumed to arise because of haploidy for the chromosome containing the mutant locus, since most cell cultures are aneuploid[4,10,11]. It is difficult to measure the mutation frequency at recessive loci in cultured haploid and diploid strains because of the paucity of haploid strains and the problems caused by aneuploidy. The slime mould *Dictyostelium discoideum*, a simple eukaryote, is suitable for this purpose, however, as both haploid and diploid strains are available[12–14] and aneuploids are so unstable or inviable that none has been isolated[14]. Using this organism, I have found, contrary to the expectation that mutant diploids should be extremely rare (say 2×10^{-12} diploid, 10^{-6} haploid)[1–6], that the difference in mutation frequency between haploids and diploids for one recessive locus is only an order of magnitude.

Isogenic haploid (NP73) and diploid (DP62) strains of *D. discoideum* able to grow in axenic medium and derived from strain V12 (K.L.W., in preparation) were used. Strains NP73 and DP62 were isolated from the same culture, and strain DP62 is a diploid, formed presumably by the parasexual fusion of two haploid amoebae of strain NP73. The fruiting bodies of both strains have a similar appearance when amoebae grown on slime mould (SM) agar plates with *Aerobacter aerogenes* are allowed to sporulate, although growth of DP62 is slightly slower and the spore masses are shorter than NP73. All 28 haploid segregants of strain DP62, obtained by prolonged growth of DP62 in axenic medium[14] or as faster growing sectors on agar plates, were indistinguishable from strain NP73. Both strains carry the spore shape marker *sprB2* (ref. 17) which makes the distinction between haploid and diploid strains very easy (Fig. 1*a* and *b*). To confirm the ploidy, both strains were grown axenically and their chromosomes were stained; NP73 has seven chromosomes and DP62 has 14 (Fig. 1*c* and *d*).

Table 1 Spontaneous frequency of occurrence of methanol resistance (*acrA*) in isogenic haploid and diploid strains of *D. discoideum*

Strain	No. of mutants*	Frequency ± s.e.
Haploid NP73	115	$7.2\pm1.6\times10^{-7}$
Diploid DP62	15†	$8.8\pm4.6\times10^{-8}$

The table shows the combined results from the examination of 1.6×10^{8} amoebae of strains NP73 and DP62. For each of eight clones, 10 methanol-containing (2% v/v) SM agar plates[17] were inoculated with 2×10^{6} amoebae and a heavy inoculum of the bacterial associate *Aerobacter aerogenes*. We had established that the frequency of occurrence of *acrA* mutants is independent of the number of amoebae plated over a wide range of inoculation densities (at least 10^{5}–2×10^{6} per plate)[17]. Resistant colonies were isolated from the methanol-containing SM agar plates after 7 d at 22 °C; no additional resistant colonies were observed at day 14. All resistant colonies were passaged on SM agar and retested on SM agar containing methanol to confirm that resistance was maintained in the absence of methanol. The plating efficiency on SM agar containing methanol (2% v/v) of two haploid and two diploid methanol-resistant strains studied further was 100%. The ploidy of all mutants was assessed by spore size and shape. The ploidy of several methanol-resistant haploid and diploid strains was confirmed by chromosome staining (Fig. 1).

*Haploids, *acrA*; diploids, *acrA*/*acrA*.

†Includes one haploid strain which is excluded in calculating the frequency.

The *acrA* locus located on linkage group II was studied because it is the only site of methanol resistance in *D. discoideum*[15,16]. The phenotype of strains with a mutation at the *acrA* locus is recessive resistance to acriflavin (100 μg ml^{-1}), methanol (2% v/v) and thiabendazole (10 μg ml^{-1})[15]. Isogenic haploid (NP73) and diploid (DP62) strains were plated on to SM agar plates containing methanol (2% v/v)[15] to obtain mutants at the *acrA* locus.

Table 1 summarises the results of experiments where 2×10^{7} amoebae of each of eight different clones of strains NP73 and DP62 were plated on SM agar plates containing 2% methanol. All experiments with haploids and diploids were conducted in identical conditions using the same batches of methanol-containing plates. All resistant mutants shown in Table 1 maintained resistance to methanol when passaged in the absence of methanol. Ploidy was determined according to spore size and shape, and in some cases chromosome numbers (Fig. 1).

Spontaneous mutations to methanol resistance in haploid strain NP73 occurred at a frequency of 7.2×10^{-7}; this is within the range reported for other haploid strains of *D. discoideum* (10^{-7}–2×10^{-6}, refs 15–18). Spontaneous methanol-resistant diploids were isolated from strain DP62 at a frequency of 8.8×10^{-8}; this was approximately eight times less than the frequency in the haploid strain. A single haploid, methanol-resistant strain was obtained from strain DP62 (Table 1). This strain probably arose either by early haploidisation of a methanol-resistant diploid, or by mutation in a haploid amoeba in strain DP62. All diploid strains of *D. discoideum* contain haploids at a low frequency, usually $<10^{-3}$.

If methanol resistance in the diploids was due to homozygosis for a recessive mutation, all haploid segregants from such a diploid would be resistant to methanol. On the other hand, if resistance arose due to a dominant mutation, only half of the haploid segregants should be resistant to methanol. To rule out the possibility of dominant alleles at the *acrA* locus, 15 independently derived haploid segregants isolated as faster growing sectors from a methanol-resistant diploid on SM agar plates were screened for methanol resistance. All were resistant, confirming observations that mutations at the *acrA* locus are recessive[15–18].

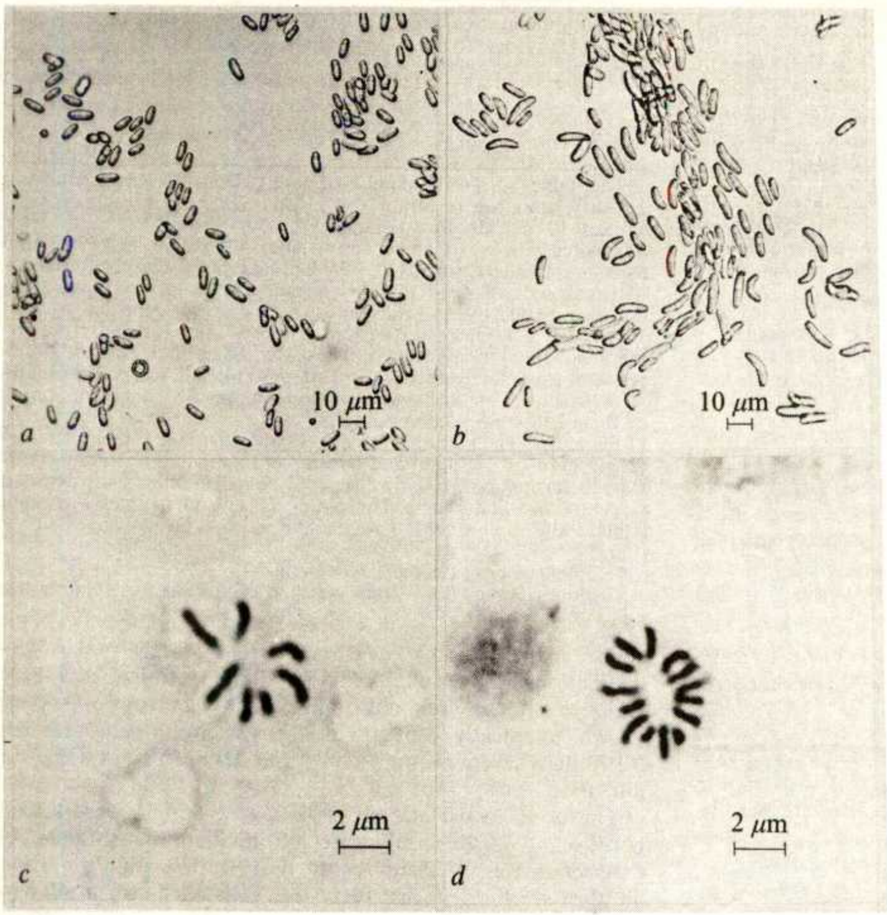

Fig. 1 *a*, Spores of haploid strain NP73 (× 300). *b*, Spores of diploid strain DP62 (× 300); the diploid spores are slightly boomerang-shaped and are considerably longer than the haploids. *c*, Late prophase of haploid strain NP73 showing seven chromosomes (× 3,250). *d*, Late prophase of diploid strain DP62 showing 14 chromosomes (× 3,250). Both strains were grown axenically and the chromosomes were fixed and stained with Giemsa stain as described previously[14].

Studies of diploid seeds of the tomato *Lycopersicon esculentum* have shown that, when the mutagen hydrazine is used, the frequency of mutants homozygous at specific recessive loci is similar to that of mutants heterozygous at the same loci[19]. Together with these results, my studies of *D. discoideum* show that the unexpectedly high frequency of mutants homozygous at recessive loci in diploids is not a unique property of cell tissue culture systems; it may even be a general property of diploid cells. An attractive hypothesis which may explain the observed high frequency of mutants at recessive loci in diploids is that they arise by a single mutation followed by recombination, for example, mitotic crossing over or gene conversion, rather than by two independent mutagenic events[6,11].

Tests of this hypothesis are in progress, using a methanol-sensitive diploid strain of *D. discoideum* with markers flanking the *acrA* locus–linkage group II, centromere, *whiA*/+, +/+, *tsgD*/+ (ref. 17). The recessive, growth-temperature-sensitive marker *tsgD* is further from the centromere than *acrA*. If methanol-resistant diploids arise by a single mutation followed by mitotic crossing over, then 50% of methanol-resistant diploids would be temperature sensitive for growth, *tsgD*/*tsgD*, provided that there is an equal probability of either homologue being mutated. Examination of 20 independently derived methanol-resistant diploids provided some support for this hypothesis, for six were growth-temperature-sensitive and 14 grew at the restrictive temperature. There are however, some problems. The high mutation frequency ($\sim 10^{-7}$) does not merely result from sequential mutation and mitotic crossing over without interaction between these processes, since the expected frequency on this basis would be approximately 10^{-10}, that is $\sim 10^{-6}$ (mutation frequency, refs 15 and 17) $\times \sim 10^{-4}$ (frequency of mitotic crossing over between the centromere and *acrA*)[15,17].

I thank Gillian Robson for technical assistance, and Richard Kessin, Peter Newell and members of the Genetics Department, Australian National University, for criticisms.

Metabolic cooperation between human fibroblasts with normal and with mutant superactive phosphoribosylpyrophosphate synthetase

METABOLIC cooperation is a form of intercellular communication by which cells in contact exchange molecules, a process providing multicellular organisms with an important mechanism for control of metabolic activity[1]. Subak-Sharpe *et al.*[2] observed contact-dependent transfer of purine nucleotides from normal cells to cells mutationally incapable of producing inosinic acid due to deficiency in hypoxanthine–guanine phosphoribosyltransferase[3]. Metabolic cooperation of this type was later also demonstrated with other enzymic markers, such as adenine phosphoribosyltransferase and thymidine kinase[4,5]. Such transfers are characterised by the normal cell being the donor and the mutant cell being the recipient, the former transferring to the latter a mutationally lacking metabolite. We report here on a new form of contact-dependent metabolic cooperation, unique in that the transfer of a metabolite occurs from a mutant donor cell to a normal recipient cell.

We were able to demonstrate this phenomenon for cultured human fibroblasts using a new enzymic marker, a mutant feedback-resistant superactive phosphoribosylpyrophosphate (PRPP) synthetase. The principle of transfer along a gradient is, however, maintained in that the donor mutant cell is metabolically more active than the recipient normal cell. This marker has been found to be the primary abnormality underlying excessive purine production in a family affected with primary metabolic gout[6,7]. The mutation is manifest in superactivity of the enzyme in the physiological cellular milieu, being due to decreased sensitivity of the mutant enzyme to feedback inhibition by several physiological intracellular inhibitors such as ADP, GDP and 2′,3-diphosphoglyceric acid. This superactivity increases availability of its reaction product PRPP, a key substrate for both *de novo* and salvage pathways of purine nucleotide synthesis. The consequent increased salvage capacity thus enables selection between normal and mutant cells, and the excessive *de novo* purine synthesis enables determination of the proportion of mutant cells in a culture containing a mixture of mutant and normal cells.

The fibroblast growth medium was modified[8] to allow survival of only the mutant cells, that is, cells possessing increased capacity to produce purine nucleotides. 6-Methylmercaptopurine riboside (6-MMP-riboside; 0.2 mM) was added to block *de novo* purine synthesis[9], and hypoxanthine (0.2 mM) and uridine (0.5 mM) were added to enable salvage synthesis of inosinic acid and uridylic acid, respectively. Experiments were designed to determine whether the capacity to resist selection in these conditions could be transferred from mutant to normal cells (for details, see Table 1). Normal and mutant cells were mixed in ratios of 1:1 and 1:3, respectively, and cocultured for 3–10 generations. Table 1 shows that the capacity of mutant cells to resist selection could be transferred to the normal cells, the degree of transfer depending on the degree of contact between normal and mutant cells during selection—the greater the proportion of mutant cells in the cell mixture and the greater the density of the cells in culture during selection, the greater the probability of contact between the mutant and normal cells. After exposure to selection of a normal–mutant cell mixture (1:1) at high cell density, the rate of *de novo* purine synthesis was similar to that found before selection, being the average of the synthesis rates of separate normal and mutant cell cultures. On the other hand, when the same mixed cultures (1:1) were exposed to selection at low cell density, the rate of purine synthesis after selection increased to approximately twofold, indicating survival of the mutant cells only. The acquired resistance of the normal cells against selection was markedly reduced when normal cells were mixed with mutant ones at a 3:1 ratio. After exposure to selection of such a cell mixture at low cell density, the surviving cells were too few to allow propagation to confluency, indicating the death of most of the normal cells. When the same 3:1 cultures were exposed to selection at high cell density, however, there were enough survivors to allow propagation, and the rate of *de novo* purine synthesis in the culture was increased to 2.5-fold compared with the preselection value. These results indicate that in this latter experiment a small proportion of the normal cells survived the selective conditions, because, if all normal cells have been killed, the rate of purine synthesis should have increased approximately to fourfold.

We are assuming that the increase in the rate of purine synthesis reflected death of the normal cells. That this was indeed the case, and that there was no increase in the rate of *de novo* purine synthesis in mutant cells, is evident from experiments in which mutant cell cultures were similarly exposed to the selective conditions. In such mutant cells the rates of purine synthesis before and after selection were found to be the same

That this metabolic cooperation was contact dependent was determined as follows. One coverglass covered with normal fibroblasts and two coverglasses covered with mutant fibroblasts were placed side by side without physical contact

Table 1 Rate of *de novo* purine synthesis in mixed normal–mutant fibroblast cultures after selection against normal cells

Source of cells	Rate of incorporation of ^{14}C-formate into purines excreted by cells into incubation medium (c.p.m. per mg protein per 6 h)		
	Before selection	After selection using:	
		Dense cultures	Dilute cultures
Normal subjects			
J.B.	8,120	All cells killed	
J.Be	12,050	All cells killed	
Subject O G. with mutant enzyme	89,293	106,301	86,668
Mixture of normal and mutant cells			
O.G.+J.B. 1:1	59,294	70,447	94,567
O.G.+J.Be 1:1	58,717	61,163	90,116
O.G.+J.Be 1:3	27,269	66,246	Too few survivors to allow propagation

Biopsies (3 mm) were removed from the forearm skin, minced, placed in Falcon Plastics sterile disposable bottles and flooded with Eagle's MEM containing Earle's Balanced Salt Solution (Gibco, F–15), 15% foetal calf serum, penicillin (100 U ml^{-1}), streptomycin (100 µg ml^{-1}) and mycostatin (25 µg ml^{-1}). Media were saturated with a 5% CO_2–95% air environment, and the bottles stoppered and incubated at 37 °C until outgrowth was apparent. Cells were subcultured and serially propagated until confluency. Cell mixtures which were prepared after trypsinisation, were cocultured for 2–3 generations. Homogeneous and mixed cultures were exposed to selection at high (25,000 cells cm^{-2}) and low (1,000 cells cm^{-2}) cell densities, by addition to the regular culture medium of 0.2 mM 6-MMP-riboside, 0.2 mM hypoxanthine and 0.5 mM uridine. The selection medium and regular medium were changed every second day. Selection was carried out for one week, after which the cultures were flooded with the regular medium and propagated until confluency Cells were collected by trypsinisation and divided into two Falcon flasks and propagated until half confluency was obtained ($0.5–1.5 \times 10^6$ cells per 75–cm^2 Falcon Plastics culture flask), at which stage the cultures were studied for the rate of *de novo* purine synthesis by measuring the incorporation of ^{14}C-formate into total purines excreted by the intact cells into the incubation medium, essentially as described previously[7,8]. The non-confluent monolayer cultures were incubated for 6 h with 10 ml fresh growth medium containing 10 µCi ^{14}C-formate. At the end of incubation, the total volume of the incubation medium, after removal of cells by centrifugation, was transferred to tubes and acidified with 2.0 ml 6 N perchloric acid; 0.2 µCi 8-^{3}H-adenine were added and the tubes thoroughly mixed and maintained at 100 °C for 1 h The hydrolysate was centrifuged and the supernatant adjusted with water to 15 ml and chilled. To each tube 7 mg adenine was added as carrier, the purine bases precipitated as purine silver complex, washed, extracted with 0.1 N HCl at 100 °C, and the radioactivity was counted Results were corrected for incomplete recovery of purines, using 8-^{3}H-adenine as reference, and related to total cell protein. For all fibroblasts, labelling of purines excreted into the medium was linear with time for at least 8 h, and, for a fixed period of incubation, was also proportional to the number of cells incubated.

in one Petri dish, and flooded with selective medium. The normal cells started to degenerate within 24 h, all dying within 1 week, whereas the mutant cells remained alive without signs of degeneration.

No attempt has been made as yet to identify the molecule, the contact-dependent transfer of which is responsible for the metabolic cooperation. Four possibilities may be considered: transfer of inosinic acid or other purine nucleotides, transfer of the enzyme PRPP synthetase or of its reaction product PRPP, or transfer of molecules containing the information for the synthesis of the mutant superactive PRPP synthetase, such as DNA or RNA. That the transferable molecule has a short lifespan in the recipient cell is indicated by the dependence of metabolic cooperation on the presence, during selection, of close contact between the mutant and the normal cells, and by the observation that prolonged contact between normal and mutant cells before exposure to selective medium does not render normal cells resistant to selection. In view of what is known about contact-dependent metabolic cooperation[1–5], the short lifespan may indicate that this molecule is either the reaction product, PRPP, or purine nucleotides. That nucleotides are transferred has already been demonstrated in other cases of contact-dependent metabolic cooperation; whether PRPP is also transferred has not yet been clarified. Nevertheless, a transfer of PRPP is likely in view of its higher concentration in the donor cell and its small molecular weight.

Altered glucose-6-phosphate dehydrogenase in bromodeoxyuridine-substituted cells

IT has been adequately demonstrated that BUdR is mutagenic in bacteriophage[1,2,3] when incorporated in place of thymidine in DNA, whereas a clear demonstration that it is mutagenic in eukaryotic cells is still lacking. We have described the selection of two variant hamster cell lines that survive with extensive levels of BUdR substitution in DNA[4,5] and that have been maintained in continuous cultivation for more than 300 generations without loss of viability. We have found no evidence of alterations in the nucleotide ratio of nuclear DNA consistent with the accumulation of BUdR-induced base transition on long term cultivation of the cells, and analysis of rRNA made in the substituted cells offers no evidence that BUdR causes base transitions within the genome or transcriptional errors which result in the accumulation of faulty RNA transcripts[6].

As a more sensitive test to detect BUdR-induced alterations in the genome or in transcription products, we have begun to examine various enzymes produced in the parent and substituted cell lines. The heat lability of an enzyme is frequently used as one criterion of an altered primary sequence of that protein. Thus, senescent WI-38 and MRC-5 cell cultures have increased fractions of heat labile glucose-6-phosphate dehydrogenase (G6PD)[7] and lactic dehydrogenase[8]; ageing mice have an increased number of inactive liver aldolase molecules[9], and cultured fibroblasts taken from patients with either progeria[10] or Werner's

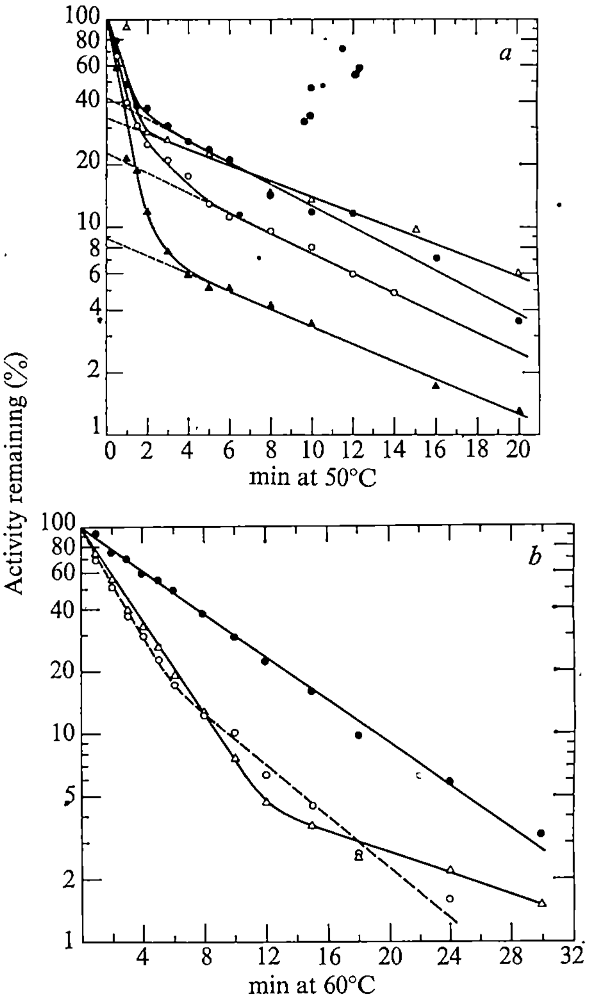

Fig. 1 *a*, Heat inactivation of G6PD from BUdR-substituted cells. Confluent roller bottles were rinsed twice with 250 mM sucrose, 1 mM EDTA, and 1 mM 2-mercaptoethanol, *p*H 8.2, and the cells were scraped off in the same solution. Subsequent steps were carried out at 4 °C. Cells were pelletted at 1,500 r.p.m. for 10 min, resuspended in the sucrose solution at approximately 10^7 cells per ml and sonicated by three bursts of 10 s each at 7 mA in a Bronwill sonicator (microprobe). Debris was removed by centrifugation at 600*g* for 10 min, and the supernatant then spun at 100,000*g* for 1 h Protein was determined by the method of Lowry *et al.*[21], and all samples were adjusted to approximately 1.5 mg protein per ml and stored in liquid nitrogen. Assays for G6PD activity contained: 50 mM Tris-HCl, *p*H 7.5, 10 mM $MgCl_2$, 1 mM NADP and 2 mM G6P. The final volume was 1 ml, containing from 0.025 to 0.2 ml of enzyme. Enzyme samples were heated at 50 °C for the appropriate time, quenched on ice and transferred to the complete reaction mixture at 25 °C. Assays were carried out at 25 °C in a Gilford 2400 spectrophotometer, following the initial rate of increase in absorbance at 340 nm due to the reduction of NADP. Activity in the unheated enzyme was dependent on the addition of both G6P and NADP. ●, 3460; ○, B4; ▲, HAB; △, a mixture of 3460 and HAB with relative G6PD activities of 2:1. *b*, Heat inactivation of G6PD isolated in the presence of 1 mM NADP. Enzyme samples were prepared and assayed as in (*a*) except that the enzyme was always in the presence of 1 mM NADP and heated at 60 °C. ●, 3460; ○, B4; △, HAB.

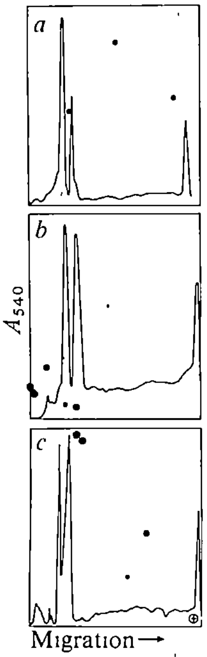

Fig. 2 Electrophoresis of G6PD on polyacrylamide gels. Samples were electrophoresed for 4 h and 3 mA per gel on 11-cm 8% polyacrylamide disk gels according to Bakay and Nyhan[21]. The running buffer was 5 mM Tris-HCl, *p*H 8 1, and 40 mM glycine. Bromophenol blue was added as a marker and ran to about 1 cm from the end of the gel at the termination of electrophoresis. Gels were stained for G6PD activity for 45 min at 37 °C in a solution containing: 100 mM Tris-HCl, *p*H 7.6, 10 mM $MgCl_2$, 0.5 mM NADP, 3.5 mM G6PD, 0.73 mM nitroblue tetrazolium, and 0.2 mM phenazine methosulphate. Gels were then fixed in 7% acetic acid and scanned at 1 cm per min for G6PD activity at 540 nm in a Gilford 2400 spectrophotometer fitted with a linear transport unit. Electrophoresis is from left to right, with the bromophenol blue marker at the extreme right. Peaks of G6PD activity are designated I and II corresponding to the most slowly and rapidly migrating, respectively. *a*, 3460; *b*, B4; *c*, HAB.

syndrome[11,12], both of which show clinical manifestations of premature ageing, have an increased fraction of heat labile G6PD, 6-phosphogluconate dehydrogenase and hypoxanthine-guanine phosphoribosyl transferase.

If BUdR is acting as a mutagen in the substituted hamster cell lines, we might expect to find differences in the heat lability and/or other enzymatic properties of some enzymes which could be the consequence of alterations in the primary sequence of proteins due to BUdR-induced base transitions during replication or transcription We report here that both *in vitro* and *in vivo* experiments have shown that substituted cells contain an altered population of G6PD molecules, which correlates well with the level of BUdR substitution in the genome.

The cell lines used have been described before[4,5]. Briefly, 3460 cells are derived from a Syrian hamster melanoma (RPMI 3460), are grown in Dulbecco's modified Eagle's medium in the absence of BUdR and routinely have a cloning efficiency of >95%. B4 cells are derived from 3460, are grown in the presence of 10^{-4} M BUdR (required for optimum growth) and have a cloning efficiency of ~90%; the nuclear DNA is 62% substituted with BUdR. HAB cells are derived from B4 by growth in media containing 0 1 mM hypoxanthine, 0.4 μM aminopterin, and 10^{-5} M BUdR; the cloning efficiency is routinely ~85% and the nuclear DNA is ⩾ 99.8% substituted with BUdR. The generation times are approximately 16, 28 and 36 h for 3460, B4 and HAB cells, respectively. Both B4 and HAB cells have undergone more than 300 population doublings without apparent loss of viability and had undergone more than 175 population doublings at the time of our experiments.

Human erythrocyte G6PD consists of a single polypeptide chain encoded for by an X-linked gene[13], and is active in both dimeric and tetrameric forms, but inactive as a monomer[14]. This is probably true of rodent cells as well[15], although the enzyme activity may be partially regulated by autosomal loci[16]. For heat denaturation studies crude enzyme preparations were made from 3460, B4 and HAB cells (in the absence of NADP). Their heat lability is shown in Fig 1*a*. The G6PD activity from all three cell lines shows a biphasic denaturation, with both a rapidly and a slowly denaturing component. When extrapolating the linear portion of the curve (slowly denaturing) to the ordinate, we calculate that the fraction of heat labile G6PD molecules in 3460, B4 and HAB cells is 59%, 77% and 91%, respectively The average fraction of heat labile G6PD molecules from four different preparations is 56.5%, 69.7%, and 79 7% for 3460, B4 and HAB cells, respectively (Table 1) This difference is not due to different protein concentrations of heated enzyme preparations since they were adjusted to nearly equal protein concentrations before heating and assay. More important, dilutions of each enzyme preparation gave the same value for the fraction of heat labile molecules on extrapolation, although the rate of decay varied with protein concentration (data not shown). It is unlikely that endogenous inhibitors or activators of G6PD activity could account for these differences since a mixture of 3460 and HAB enzyme extrapolates intermediate to the two assayed individually (Fig. 1*a*). This enzyme mixture contained a G6PD activity ratio of 2:1 (3460:HAB), expected to yield, therefore, a value of 69% heat labile (using the value of 59% and 91% heat labile G6PD for 3460 and HAB cells, respectively). The extrapolation was to 66% heat labile. As human G6PD is stabilised in the presence of NADP[14], we have examined the ability of NADP to stabilise G6PD against heat denaturation. When 3460 enzyme was incubated with ⩾ 10 μM NADP for 20 min at 4 °C before heat denaturation, we detected no inactivation of G6PD at 50 °C for up to 30 min, whereas ⩾ 50 μM NADP is required to stabilise fully B4 and HAB cell G6PD at this temperature (in the presence of 25 μM NADP, HAB enzyme was 25% denatured within 20 min). In as much as NADP is shown to stabilise all three enzyme preparations to some extent, it was possible that heat lability differences were due to different intracellular amounts of NADP and, thus, differential inactivation during isolation. Therefore, enzyme preparations were isolated in the presence of 1 mM NADP and heat inactivation studies carried out at 60 °C. These results are shown in Fig 1*b*, from which we calculate the fraction

Table 1 Properties of G6PD from BUdR-substituted cells

Enzyme (cell line)	% Heat labile*	K_m† NADP (μM)	G6P (μM)	dG6P utilisation‡
3460	59,56,58,53 (56.5)	14.5±1	33±2	7.5±0.2
B4	77,66,69,67 (69.7)	20.7±1	33±2	8.9±0.2
HAB	91,74,78,76 (79 7)	23 0±1	33±2	10.7±0.3

*Values are from four different enzyme preparations and their mean (shown in parentheses).

†K_ms were determined after dialysis of the enzyme preparations (isolated in the absence of NADP) against 250 mM sucrose, 1 mM EDTA and 1 mM 2-mercaptoethanol for 16 h at 4 °C. NADP was assayed from 1 to 200 μM and G6P from 5 to 300 μM, in triplicate (± s.d.)

‡Percentage of glucose-6-phosphate utilisation (determined in triplicate from two enzyme preparations, ± s.d.), after dialysis for 16 h.

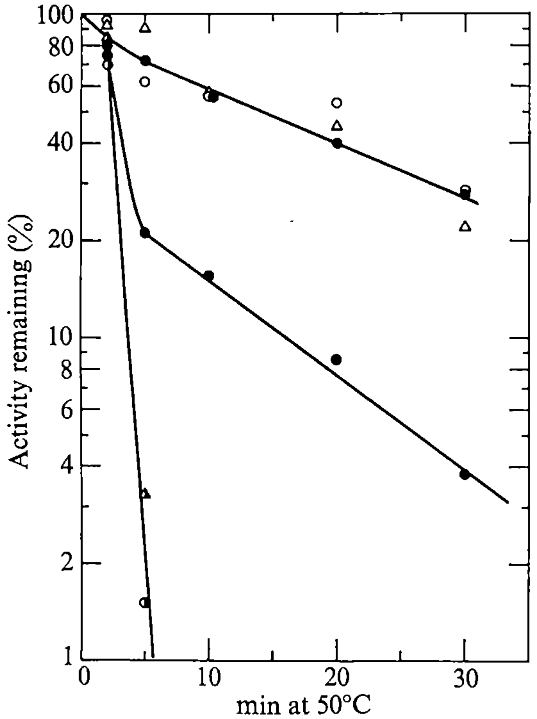

Fig. 3 Heat inactivation of G6PD activities I and II. Enzyme samples (isolated in the absence of NADP) were heated at 50 °C for various times as described in Fig. 1*a* and then subjected to electrophoresis as described in Fig. 2. Gels were stained for G6PD activity for 45 min at 37 °C, fixed in 7% acetic acid, and then scanned at 540 nm to measure the rate of loss of activities I and II as a function of heating time. All values are plotted as the % activity in the respective peaks relative to unheated controls (the average of quadruplicate gels). ●, 3460; ○, B4; △, HAB. Top curve, peak I; lower two curves, peak II.

of heat-labile G6PD in B4 and HAB cells to be 62% and 91%, respectively. In these conditions, 3460 enzyme decayed linearly.

Criteria used to characterise the large number of human G6PD variants[17] include altered *p*H optima, altered K_m for NADP and glucose-6-phosphate (G6P), and the utilisation of 2-deoxy-D-glucose 6-phosphate (dG6P), an analogue of G6P Table 1 shows that all three cell lines had the same K_m for G6P, but differed in their K_m for NADP. Furthermore, B4 and HAB cell G6PD had a slightly greater ability to utilise dG6P as a substrate. All three enzymes showed *p*H optima at 7.5 and 8.5 with only minor differences at the extremes of the curves (*p*H 7.0 and 10.0), not unlike many of the human variants[17].

We could not detect different electrophoretic mobilities of G6PD from the three cell lines on cellulose acetate (frequently used to detect human variants) and have used instead polyacrylamide disk gels, where we have been better able to quantitate enzyme activity on the gel (Fig. 2). Two major peaks of activity were observed for all three cell lines with R_f of 0.22 (peak 1) and 0.28 (peak 2), although the relative proportions of peaks 1 and 2 differed significantly. Thus, the relative amounts of peaks 1 and 2 were routinely found to be 69:31, 52:48, and 28:72 for 3460, B4 and HAB cell G6PD, respectively. (These values varied by ±5% on duplicate gels and with different preparations.)

The increasing proportion of peak 2 in B4 and HAB cell G6PD suggests the possibility that this activity is largely responsible for the increasing fraction of heat labile G6PD in BUdR substituted cells. This possibility was tested by heating the enzyme samples at 50 °C for various times, electrophoresing the enzyme, and determining the fraction of activity remaining in each of the two activity peaks (Fig. 3). Peak 1 decayed at approximately the same rate for all three cell lines. Peak 2 from 3460 cells decayed at a somewhat greater rate than peak 1, whereas peak 2 from B4 and HAB cells decayed substantially faster. Only negligible activity remained after 5 min at 50 °C, making quantitation of activity on the gels difficult.

We have sought to confirm the presence of an altered population of G6PD molecues in B4 and HAB cells using the histochemical staining method described by Wajntal and DeMars[18]. In particular, we have used this assay to determine if a higher proportion of B4 and HAB cells in monolayer can be shown to utilise the substrate analogue dG6P. After growth in monolayer for 24 h, all three cell lines were stained for G6PD activity using G6P or dG6P, or in the absence of substrate. Cells were scored as being stained or unstained at both low magnification and high magnification. This analysis provides an absolute number for cells staining positive under high magnification (where cells with only a few blue granules of formazan are readily discernable), as well as information on the relative intensity of staining (as the ratio of cells staining positive at high magnification/low magnification).

The percentage of cells stained positive for G6PD activity in the presence of both substrates is given in Table 2. Under low magnification, an equivalent number of cells stained positive (~76%) in the presence of G6PD for all three lines, whereas about twice as many B4 and HAB cells were positive in the presence of dG6P compared with 3460. Fewer than 1.0% of the cells were positive in the absence of substrate. Since the scoring of cells at low magnification is somewhat subjective, a better analysis of positive cells was obtained under high magnification. In these conditions the percentage of positive cells in the absence of substrate increased, and there were significant differences between the substituted and unsubstituted cell lines, with 14% of the HAB cells scored positive compared with 5.9% of 3460 cells. This may reflect higher endogenous levels of G6P in the slower growing B4 and HAB cells. Nevertheless, the number of positive cells in the presence of either G6P or dG6P increased under high magnification and when corrected for the difference in background staining (minus substrate), all three cell lines had an equivalent number of cells stained positive in the presence of G6P. After correction for background staining, however, B4 and HAB cells had a substantially higher propor-

Table 2 Percentage of cells positive for G6PD activity

	Cell line		
Substrate	3460	B4	HAB
	Low magnification (×125)		
G6P	73.3 (1,943)	76.6 (1,919)	78.5 (1,867)
dG6P	11.1 (1,473)	21.1 (1,325)	22.5 (1,146)
None	<1.0 (937)	<1.0 (889)	<1.0 (1,042)
	High magnification (×500)		
G6P	86.3 (1,212)	92 4 (956)	93.9 (872)
dG6P	26.7 (1,077)	62.4 (996)	69.0 (919)
None	5.9 (702)	12.9 (726)	14.0 (714)
	Corrected*		
G6P	80.3	79.5	79.9
dG6P	20.7	49.5	55.0
	High magnification/low magnification ratio		
G6P	1.09	1.04	1.02
dG6P	1.86	2.35	2.44

Cells in monolayer were stained for G6PD activity essentially as described by Wajntal and DeMars[18]. Flaskettes (Lab-Tek) were innoculated with 10^5 cells which were grown for 24 h. Media was then removed and each Flaskette was rinsed with 5 ml of 0.9% NaCl. Staining solution (2.5 ml) was added and the Flaskettes were incubated for 1.5 h at 37 °C. The staining solution consisted of: 0.1 M Tris *p*H 7.8, 0.5 mM $MgCl_2$, 0.2 mM NADP, nitroblue tetrazolium (0.5 mg ml $^{-1}$), phenazine methosulphate (0.02 mg ml^{-1}) and 6 mM G6P or dG6P (or no substrate). The plastic cover was removed from the Flaskette and the slide was rinsed in distilled water and counterstained in alcoholiceosin. Cells were scored for blue deposits of formazan at either ×125 or ×500. Numbers of cells scored are given in parentheses.

*Percentage of cells scored positive in the absence of substrate at high magnification subtracted.

tion of cells (× ~2.5) stained positive with dG6P as substrate when compared with 3460 cells. Using the ratio of positive cells at high magnification/low magnification, all three cell lines stained similarly in the presence of G6P (ratio ~1.1), whereas in the presence of dG6P this ratio increased in the B4 and HAB cells, suggesting an increasing fraction of lightly stained cells in the BUdR substituted populations. This consistency in the ratio of high magnification/low magnification in the presence of G6P for all three cell lines suggests that this difference was not due to higher endogenous G6PD levels in the B4 and HAB cells.

Thus, B4 and HAB cells contain a greater fraction of heat labile G6PD molecules than the parent, unsubstituted, cell line. When enzymes are isolated in the absence of NADP, the 3460 cells also have a high level of heat labile G6PD. Using 56.5% heat labile G6PD in 3460 cells (Table 1) as a baseline and 79.7% heat labile G6PD in HAB cells as the effect of 100% BUdR substitution, we would predict that if BUdR is randomly generating mutations or transcriptional errors (which would be a function of the level of BUdR substitution), cells which are 62% substituted (B4) should contain a population of G6PD molecules of which 69.7% are heat labile. We found an average of 70.8%. When enzymes are isolated in the presence of NADP, 3460 G6PD shows a linear decay whereas B4 and HAB are still 62% and 91% heat labile, respectively. Using the extreme values of 3460 (0%) and HAB (91%), we would predict 56% heat labile for B4 on the basis of BUdR substitution, not far from the 62% observed.

Perhaps the clearest demonstration of an altered G6PD in B4 and HAB cells is the difference in the relative amounts of peaks 1 and 2 obtained by electrophoresis on polyacrylamide gels, and the substantial difference in the heat lability of peak 2. Bakay and Nyhan[19] separated human G6PD into three bands of activity by polyacrylamide disk gel electrophoresis, with mobilities similar to the two major bands resolved from the cells used here. The bands of human G6PD activity are interconvertible by NADPH-producing substances, suggesting that the bands are conformers with and without bound NADP[20]. Furthermore, agents which adversely affect the binding of NADP to the enzyme (such as NADPH) promote formation of the more rapidly migrating band. We therefore propose that peak 2 of G6PD activity in the cells examined here represents the enzyme form without bound NADP. When gels were run in the presence of NADPH, the enzymes from all three cell lines migrated as a single band with an R_f of 0.28, similar to peak 2 (unpublished observations). This finding is consistent with the B4 and HAB cell G6PD being deficient in NADP binding.

The fact that B4 and HAB cell G6PD has a higher K_m for NADP and an increasing proportion of peak 2 activity which is extremely heat labile suggests the presence of an altered ("variant") population of G6PD molecules, at least some of which may have altered in their NADP binding by amino acid substitution. The correlation between the fraction of heat labile G6PD and the extent of BUdR substitution suggests that BUdR may be acting as a mutagen, generating a number of variant G6PD molecules in the B4 and HAB cell lines, or alternatively, that these "variants" represent the products of transcriptional errors induced by BUdR. Although we have been unable to detect transcriptional errors by direct nucleotide analysis[6], the analysis of enzymes as reported here is expected to be a more sensitive method of detecting a low level of base (and hence, amino acid) changes. A mutagenic role for BUdR (including transcriptional errors) is somewhat paradoxical in light of the continued viability of the B4 and HAB cell lines. While it seems to offer the most satisfactory explanation of our results, several other enzymes from these cell lines will have to be examined before this question can be answered conclusively.

We thank Bryan Cullen for technical assistance.

Note added in proof: Recent experiments have ruled out a heritable mutational origin for the faulty G6PD and suggest a transcriptional origin.

Decreased levels of an inhibitor of prostaglandin E 9-ketoreductase activity in chick dystrophic breast muscle

A WIDE range of membrane anomalies is one of the characteristics of dystrophic muscle[1,2]. Since prostaglandins (PGs) are known to interact with such membrane constituents as adenyl and guanyl cyclase; Mg^{2+}-dependent, Na^+/K^+-activated ATPase; Mg^{2+}-dependent, Ca^{2+}-activated ATPase; adenylate kinase; and phosphodiesterase[3], it seemed desirable to search for a possible relationship between PGs and the dystrophic condition. The activities of two potentially regulatory PG-metabolising enzymes were measured. NAD^+-dependent 15-hydroxyprostaglandin dehydrogenase activities[4] in the breast muscles of 10-d post-hatching chicks with hereditary muscular dystrophy (New Hampshire strain) and the breast muscles of 10-d post-hatching normal (white leghorn) chicks were the same as those in the leg muscles of these animals. PGE 9-ketoreductase activity[5,6] in the dystrophic breast muscle was considerably more active than its control (normal) breast muscle. Subsequently, it was found that the normal breast muscle contains a much higher level of an inhibitor of PGE 9-ketoreductase activity than dystrophic breast muscle.

The assay system used to measure PGE 9-ketoreductase activities consisted of increments of cytoplasmic fractions of the muscle extracts, 1.0 μg PGE_2, and 1.0 mM NADPH. Enzymatic generation of $PGF_{2\alpha}$ was measured by radioimmunoassay with antibodies directed against $PGF_{2\alpha}$. When the cytoplasmic fractions were tested for their effect on the activity of exogenous PG 9-ketoreductase, the enzyme purified from chicken heart[5] was used. This amount of PGE_2 9-ketoreductase catalysed the generation of 50 ng $PGF_{2\alpha}$ after incubation for 15 min at 37 °C. In these experimental conditions, the initial velocity of the catalytic reaction of the purified enzyme is being measured. Analyses of these reaction mixtures by thin-layer chromatography confirmed the enzymatic conversion of PGE_2 to $PGF_{2\alpha}$. Extracts of the various breast and leg muscles from normal and hereditary dystrophic chicks were made as follows: chicks were decapitated, and the muscles excised and immediately frozen in liquid nitrogen. For extraction, the individual muscles were suspended in 0.092 M phosphate buffer, *p*H 7.3, 0.1 mM dithiothreitol (1.0 g muscle per 4.0 ml buffer) and homogenised using a Sorval Omni homogeniser at full speed for 1 min at

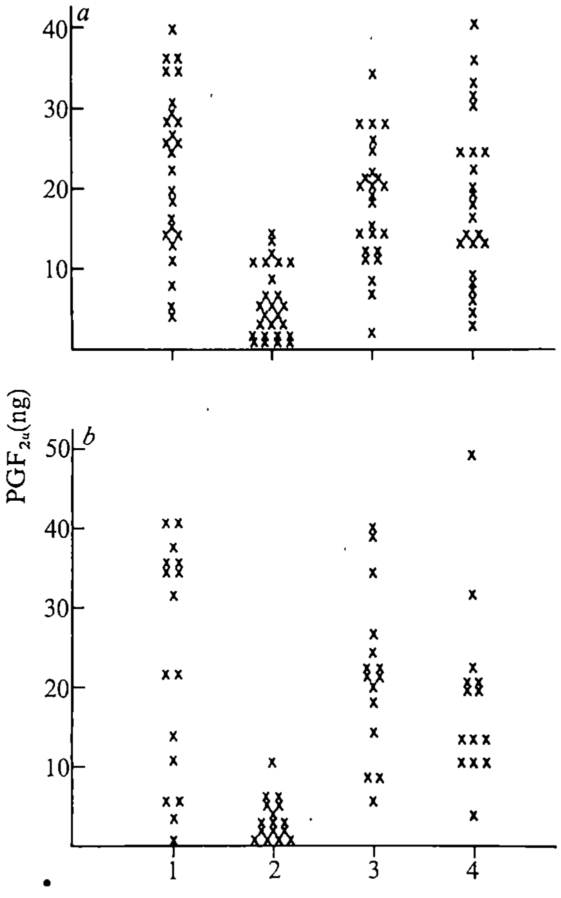
0 °C. After stopping the mixer for 5 min, the muscle suspension was homogenised again for an additional minute. After centrifugation at 10,000g for 20 min, the supernatant fluid was recentrifuged at 100,000g for 1 h, and this supernatant fluid used as the cytoplasmic fraction. Analyses of these cytoplasmic fractions for protein showed that the efficiencies of protein extraction from the four muscles were similar.

PGE 9-ketoreductase activities in terms of ng $PGF_{2\alpha}$ generated from 1.0 μg PGE_2 by 50 and 100 μl cytoplasmic fractions from normal and dystrophic breast muscle (10-d post-hatching), and from the leg muscles of these same chicks, are shown in Fig. 1. Values for the dystrophic breast muscle fall into the same range as those for normal leg muscles and symptom-free leg muscles from the dystrophic chicks. Values for normal breast muscles, on the other hand, are clustered around a much lower level. On increasing the amount of muscle extract from 50 to 100 μl (Figs 1*a* and *b*, and 2*a*) added to the reaction mixture, a disproportionately small increase (even a decrease with normal breast muscle) in $PGF_{2\alpha}$ formation was observed, indicating the presence of an inhibitor in these muscle extracts.

To test this possibility, the effect of extracts from the four types of muscle from two chicks on PG 9-ketoreductase purified from chicken heart was studied. The extracts from normal breast muscle (both the 10-d post-hatching chick and an adult normal chicken) depressed the activity of this preparation considerably more than extracts from dystrophic breast muscle and the leg muscles (Fig. 2*b*). Addition of increasing amounts of extract from the normal breast muscles of the young chicks to the purified PGE 9-ketoreductase first increased enzymatic activity, presumably due to PGE 9-ketoreductase present in the extract, then actually decreased the reductase activity. In the presence of extracts of dystrophic muscles and the leg muscles, reductase activity was also increased; but with higher concentrations of these extracts, the degree of increase in reductase activity was reduced, and in the presence of 100 μl the reductase activity was even inhibited. If the inhibitor in the dystrophic breast muscle and the leg muscles is identical to that present in the normal breast muscle, the normal breast muscle contains 5 to possibly 50 times more of it. An inhibitor of PGE 9-ketoreductase has been partially purified from normal adult breast muscles of chickens. This inhibitor seems to contain a flavin-related moiety. Whether it is identical to the inhibitor found at reduced levels in dystrophic breast muscle is still to be demonstrated.

The effect of 50 μl of the four muscle extracts from several chicks on purified PGE 9-ketoreductase activity is shown in Fig. 3. Again it can be seen that levels of inhibition of the reductase by normal breast muscle are much higher than that of dystrophic breast muscles or the leg muscles. The findings

Fig. 1 Enzymatic production of $PGF_{2\alpha}$ by 50 (*a*) and 100 μl (*b*) cytoplasmic fractions of four muscle preparations from individual animals. 1 and 2, Breast muscle: 1, dystrophic chick; 2, normal chick. 3 and 4, Leg muscle: 3, dystrophic chick; 4, normal chick. Enzymatic reaction mixtures, containing the cytoplasmic fractions, 1.0 μg PGE_2 and 1.0 mM NADPH in a total volume of 0.1 ml, were incubated for 15 min at 37 °C. The reaction was stopped by boiling for 2 min. After addition of 0.9 ml buffer, the denatured protein was removed by centrifugation, and $PGF_{2\alpha}$ estimated by radioimmunoassay[4]



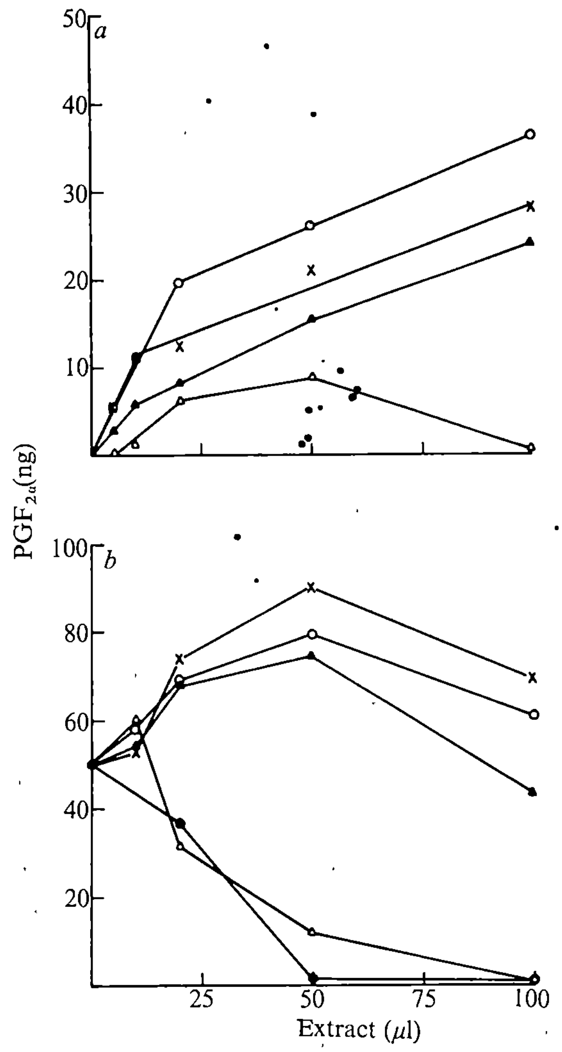


Fig. 2 Enzymatic production of $PGF_{2\alpha}$ by increments of cytoplasmic fractions from four muscle preparations from two chicks (*a*) and these same cytoplasmic fractions in the presence of a constant amount of PGE 9-ketoreductase purified from chicken heart (*b*). ×, Dystrophic breast muscle; △, normal breast muscle; ▲, normal leg muscle; ○, symptom-free leg muscle from dystrophic chick; ●, normal breast muscle from adult chicken. Experimental conditions in *a* are the same as those described in Fig. 1. In *b*, increments of cytoplasmic fractions, purified PGE 9-ketoreductase, 1.0 μg PGE_2 and 1.0 mM NADPH in a volume of 0.1 ml, were incubated for 15 min at 37 °C. After boiling for 2 min followed by addition of 0.9 ml buffer and centrifugation, the supernatant fluid was assayed for $PGF_{2\alpha}$ by radioimmunoassay.

that the low activities of NAD+-dependent 15-hydroxyprostaglandin dehydrogenase in our experimental conditions are the same in normal and dystrophic breast muscle extracts suggest that the increased $PGF_{2\alpha}$ levels in the presence of the dystrophic muscle extracts did not reflect differences in enzymatic oxidation of the 15-hydroxy group.

The presence of different levels of inhibitor of PGE 9-ketoreductase can be added to the properties which distinguish the normal pectoralis (white) muscle from the thigh and leg (red) muscle of the chick[7]. In contrast, this distinction is absent in the dystrophic pectoralis which shows a low level of the inhibitor similar to that of the leg muscle. The properties which distinguish pectoralis (white) leg or heart (red) muscle appear during the last third of embryonic development and the first month of post-hatching. The retardation of the full development of the characteristics of white muscle in the dystrophic pectoralis has been demonstrated with regard to several cell properties[8]. Similarly, one could see in the absence of the PGE 9-ketoreductase inhibitor in dystrophic pectoralis another instance of a suppression of late development.

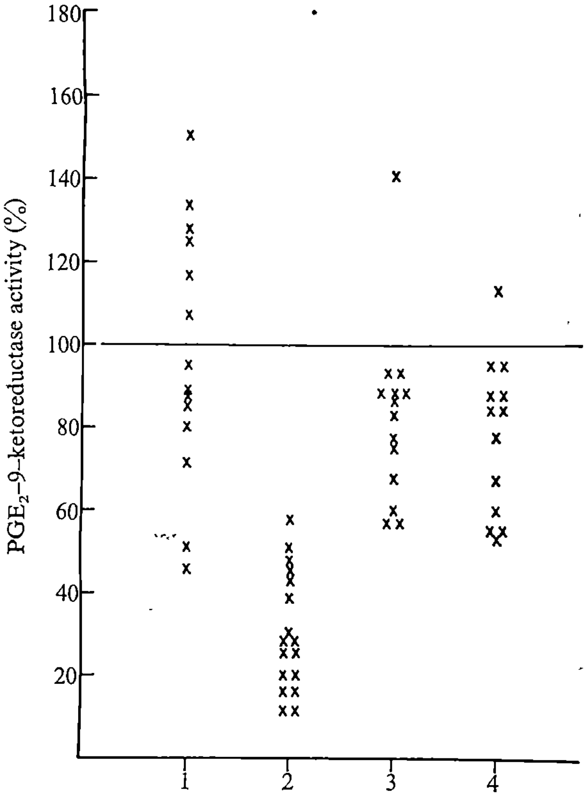

Fig. 3 PGE 9-ketoreductase activity of 50-µl cytoplasmic fractions of the four muscle (for code, see Fig 1) extracts from individual chicks in the presence of a constant amount of PGE 9-ketoreductase purified from chicken heart Enzyme activity is expressed as percentage of that obtained with purified enzyme. Experimental conditions are the same as those in Fig 2*b*.

Different profiles of prostaglandin metabolism have been found in the lung and kidney of foetal and early newborn rats and in adult rats[9,10]. It is possible that the PG system, which includes generation of endoperoxides, thromboxanes, and the primary PGs, have an important role in differentiation. The fact that certain nutritional muscle dystrophies can be induced by a deficiency of an antioxidant such as tocopherol[11], that in these conditions peroxidation of lipids can be demonstrated[12], and that progress of chick dystrophy is retarded by sulphydril-protecting substances such as penicillamine[13], could point to involvement of PG-derived peroxides in the dystrophic degeneration of chick breast muscle. How the relative levels of PGE and $PGF_{2\alpha}$ or the altered PGE 9-ketoreductase activity in the dystrophic breast muscle modulates the thromboxane pathway or endoperoxide stability (if they do indeed have a regulatory role) is not clear.

We thank the US Public Health Service (National Institute of Child Health and Development) and the Muscular Dystrophy Association for support; and Dr L. J. Pierro (Department of Animal Genetics, University of Connecticut) for making the dystrophic and control chickens available to us. L.L. and H.H. are American Cancer Research Society Professors.

C fragment of lipotropin has a high affinity for brain opiate receptors

THE C-terminal region of lipotropin, named C fragment[1], has been found as an intact polypeptide in the pituitary gland[2] and the C fragment is also released from lipotropin by mild digestion with trypsin *in vitro*[1]. These data suggest that the C fragment of lipotropin might be elaborated *in vivo* in order to perform a physiological function.

Recent reports have shown that in pituitary there is an endogenous peptide with opiate activity[3,4] and similar peptides have been found in brain[5–7]. One of the brain peptides, termed methionine enkephalin, was isolated and described as a pentapeptide with the sequence Tyr–Gly–Gly–Phe–Met[8], which is the same as the sequence at the NH_2-terminus of the C fragment of lipotropin. Although lipotropin[9] and its C fragment[1,2] were isolated from pituitary whereas the pentapeptide was isolated from brain[8], it nevertheless seems probable that methionine enkephalin is derived *in vivo* from lipotropin C fragment. We have therefore determined whether C fragment, and a series of peptides that might be formed from C fragment *in vivo*, has a high affinity for brain opiate-binding sites. The results show that several of the peptides bind strongly to brain opiate receptors and, in particular, that C fragment has a higher affinity than the pentapeptide methionine enkephalin.

Lipotropin, C fragment (residues 61–91 of lipotropin), C′ fragment (61–87), β-melanotropin (41–58) and N fragment (1–38) were isolated from pig pituitary as described previously[1]. The peptide representing residues 61–89 was isolated from a carboxypeptidase A digest (Worthington) of C fragment. The octapeptide and nonapeptide representing residues 61–68 and 61–69 of lipotropin were obtained by enzymic digestion of C fragment with *Armillaria mellea* protease (Arven) and TPCK-trypsin (Worthington) respectively; the peptides were isolated by ion-exchange chromatography on columns of Dowex 50-X2 with volatile pyridine buffers and were desalted on Sephadex G-10. The fragment containing residues 70–79 of lipotropin was isolated from the tryptic digest of C fragment. The peptides were characterised by N- and C-terminal analysis[10,11] and by amino acid composition[12]. The tetrapeptide and pentapeptide representing residues 61–64 and 61–65 of lipotropin were prepared by solid phase peptide synthesis[13]; the products were purified by chromatography on Sephadex C-25 and Sephadex A-25 and chemical and optical purity were confirmed by thin-layer chromatography and by digestion with aminopeptidase M (Röhm).

The peptides were tested for their ability to reduce the binding of the radiolabelled opiate agonist, ^{3}H-dihydromorphine, and the antagonist ^{3}H-naloxone to a membrane preparation from rat brain. The experimental details are given in Table 1. The concentrations of peptides that reduce the specific binding by 50% (I_{50}) are shown, together with the corresponding values for four opiate drugs. The determinations were made at 100 mM sodium concentration, conditions in which the I_{50} values for displacement of bound naloxone have been shown to correlate with pharmacological potency[14].

C fragment at low concentration was effective in displacing specifically bound ^{3}H-naloxone. The I_{50} value (2.6×10^{-9} M) was one tenth of that of morphine or dihydromorphine and was comparable with that of naloxone. Methionine enkephalin (61–65) and the intermediate peptides, 61–68, 61–69 and 61–87, were approximately 30 times less potent than C fragment. The I_{50} values of the closely related peptides 61–87 and 61–89 differed by a factor of 20, indicating the importance of the paired lysine residues (88 and 89) to binding affinity. Lipotropin, which includes the C fragment sequence, and seems to be the precursor of C fragment[15], did not inhibit the binding of ^{3}H-naloxone or ^{3}H-dihydromorphine, and fragments of lipotropin that lacked the C-terminal sequence were also inactive.

When the I_{50} values were obtained from competition

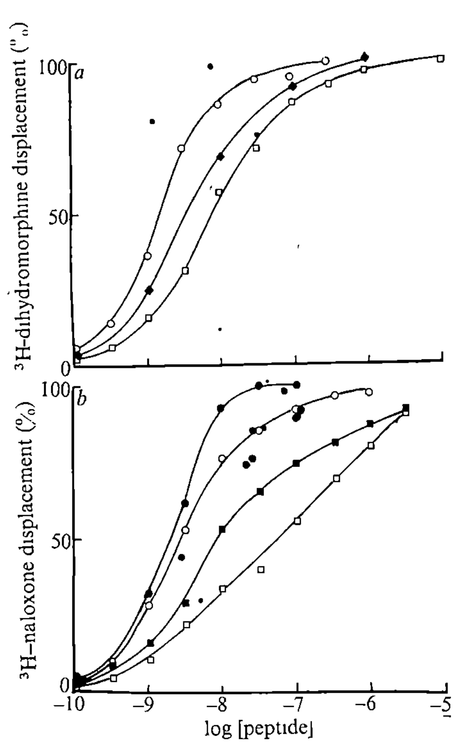

Fig. 1 *a*, Displacement of specifically bound ^{3}H-dihydromorphine by C fragment (○), methionine enkephalin (□) and morphine (◆) in Tris-HCl, (*p*H 7.4), 100 mM NaCl. Incubation conditions are described in the legend to Table 1. *b*, Displacement of specifically bound ^{3}H-naloxone by C fragment (circles) and methionine enkephalin (squares) Open symbols refer to incubations in Tris-HCl, (*p*H 7.4), 100 mM NaCl; closed symbols refer to incubations in Tris-HCl (*p*H 7.4), 100 mM KCl. KCl was included in the 'low sodium' incubation to distinguish the specific effects of sodium from nonspecific ionic strength effects. The effect of substitution of sodium by potassium in the incubation medium is to increase the specific ^{3}H-dihydromorphine counts bound by 30–40% and to decrease the specific binding of ^{3}H-naloxone by 50% Note that, in general, these curves do not represent simple mass action binding processes.

Table 1 The binding of lipotropin fragments to brain opiate receptors

Residue Nos.	Name	I_{50} against ^{3}H-naloxone M × 10^{9}	I_{50} against ^{3}H-dihydromorphine M × 10^{9}	Potency ratio: I_{50} naloxone / I_{50} dihydromorphine
61–91	C fragment	2.6	2.2	1.2

	Dihydromorphine	22	3.6	6
	Naloxone	1.8	2.4	0.7

Opiate binding assays were carried out on a hypotonically lysed (10 mM Tris-HCl, *p*H 7.4), extensively washed, crude synaptosome preparation from whole supratentorial rat brain. The membranes (0.5 mg protein ml^{-1}) were preincubated for 15 min at 30 °C in a buffer containing 50 mM Tris-HCl (*p*H 7.4) and either 100 mM NaCl or KCl. Tritiated opiates (G)-^{3}H-naloxone (New England Nuclear, 20 Ci mmol^{-1}, 1.0×10^{-9}M) or 1,7,8-^{3}H-dihydromorphine (Radiochemical Centre, Amersham, 90 Ci mmol^{-1}, 3.5×10^{-10} M) and appropriate concentrations of unlabelled opiates or peptides were added to 1-ml aliquots of preincubated membrane suspension in plastic microcentrifuge tubes After 15 min incubation in the dark, the suspension was centrifuged (14,000*g*, 2 min), the pellets rapidly and superficially washed with 100 mM NaCl or KCl, and bound radioactivity assayed by liquid scintillation counting at 30% efficiency. Specific binding was defined as that fraction of the bound radioactivity displaced by morphine (10^{-5} M) or levorphanol (10^{-6} M). Incubations were carried out in quadruplicate and the standard error of the mean of a determination rarely exceeded 3% Of 70,000 d.p.m. ^{3}H-dihydromorphine in each assay, 2,700 d.p.m. are bound specifically and 1,500 d.p.m bound nonspecifically. For ^{3}H-naloxone, of the 46,000 d.p m. in each incubation, 4,500 d.p.m. are bound specifically and 3,000 d.p.m. nonspecifically. The I_{50} value represents the concentration of the compound at which 50% of specifically bound radioactivity is displaced.

experiments against ^{3}H-dihydromorphine (Table 1), C fragment was found to have twice the potency of morphine, and methionine enkephalin had approximately one half the potency (Fig. 1*a*). The tetrapeptide (61–64) and peptides intermediate between C fragment and methionine enkephalin were less potent than the pentapeptide. The active peptides and the opiate alkaloid agonists exhibited higher potencies when assayed against ^{3}H-dihydromorphine than against ^{3}H-naloxone. The change in I_{50}, reflected in the potency ratio (Table 1), was most marked in the case of methionine enkephalin and least for C fragment. Thus C fragment behaves more like the antagonist naloxone than the potent agonists morphine and levorphanol.

Replacement of sodium ions in the assay medium by potassium resulted in a large decrease (ninefold) in the I_{50} value for displacement of bound ^{3}H-naloxone by methionine enkephalin but had only a small effect (1.3-fold) on the I_{50} value of C fragment (Fig. 1*b*). With morphine-like alkaloids it has been observed that a large sodium effect correlates with agonist properties[16–19]. Although such a correlation has not been demonstrated for opiate peptides, the results for methionine enkephalin agree with its reported agonist properties[8]. In contrast, C fragment exhibited a much smaller sodium effect. Experiments to test the pharmacological properties of C fragment are in progress[21].

Preliminary studies of the time course of C fragment binding suggest that the peptide interacts with the receptor more slowly than dihydromorphine. Thereafter, the extent of inhibition of ^{3}H-dihydromorphine binding by C fragment remains approximately constant for 2 h. Inhibition by methionine enkephalin, on the other hand, decreases slowly after 20 min, consistent with slow proteolytic degradation of the pentapeptide. The possibility that C fragment might be weakly active but undergoes proteolytic cleavage to yield a more active peptide is unlikely because the 61–64, 61–65, 61–68, 61–69 and 61–87 peptides were less active than C fragment in the binding assay. Furthermore, degradation by a trypsin-like enzyme is highly unlikely because lipotropin, which readily undergoes cleavage *in vitro* to give C fragment[1], was inactive. Certainly, in our assay conditions, C fragment does not undergo conversion to methionine enkephalin as the binding properties of the two peptides are quite different.

The binding studies indicate that a series of peptides derived from lipotropin can inhibit the binding of naloxone and dihydromorphine to brain opiate receptors. The 'active' peptides all contain the N-terminal sequence Tyr–Gly–Gly–Phe, retaining a potential for the β-bend predicted for the receptor conformation of enkephalin[20]. The most active peptide is C fragment, with an affinity substantially greater than that of methionine enkephalin. The high affinity exhibited by C fragment for brain opiate receptors *in vitro* suggests that this peptide, if present in higher regions of brain, could function *in vivo* as a neurotransmitter or neuromodulator.

We thank Sir Arnold Burgen for advice and assistance, and Pramila Mehta and Derek Massey for technical help. We also acknowledge gifts of morphine from Professor W. S. Feldberg, levorphanol tartrate from Roche Products Limited, Welwyn Garden City, Herts., dihydromorphine from Professor H. W. Kosterlitz and *Armillaria mellea* protease from Dr H. Gregory.

Since this manuscript was submitted, the C fragment has been tested *in vivo* by Professor W. S. Feldberg using direct injection into the 3rd ventricle of the cat: it was found to have potent analgesic properties, the effects lasting several hours[21]. In molar terms, C fragment was approximately 200 times more potent than morphine.

Structural and conformational relationships between the enkephalins and the opiates

Two pentapeptides, the enkephalins (Fig. 1*a*), have been isolated from the mammalian brain and have been shown to be potent opiate agonists[1,2]. Further work has demonstrated that the opiate analgesics themselves interact competitively with the receptor sites for these endogenous pentapeptides. This explains in a simple and elegant manner the occurrence of opiate receptors in nervous tissue[3,4]; clearly it was unlikely that they were there to interact solely with the opiates. As the enkephalins and opiates are competing for the same receptors and give a similar pharmacological response it is likely that they have structural and conformational similarities. Hughes *et al.* have shown that both of these small peptides contain a tyrosine residue at the amino terminal position[2]. We consider here the significance of that finding for the conformational relationship between the enkephalins and opiates.

The discovery that tyrosine is in a terminal position rather than in the internal sequence, where the nitrogen atom would be part of an amide linkage and therefore not basic, is of considerable significance. If we make the reasonable assumption that the primary locus of interaction of the above peptides with the opiate receptor is at the tyrosine terminal, then this would explain why the 'tyramine' portion of the tyrosine residue (Fig. 1*a*) is a common feature of many of the most potent groups of opiate analgesics such as the morphines (Fig. 1*b*), morphinans (Fig. 2*a*) and 6,7-benzomorphans (Fig. 2*b*). As several antagonists are derived from the above agonists similar considerations will also apply to these drugs. The 3-OH morphinans (Fig. 2*a*, levorphanol) and 2′-OH-6,7-benzomorphans (Fig. 2*b*, metazocine) are as potent as or more potent than morphine; therefore it is obvious that these simplifications of the morphine skeleton, which are considerable in the case of the benzomorphans, still contain the active moiety. The development of various elegant *in vitro*[3,4] methods of assessing opiate agonist and antagonist activity has removed some of the problems of structure–activity correlations based simply on *in vivo* measurements where factors other than opiate receptor interaction may distort accurate interpretations. The fact that the tyramine fragment of the enkephalins has a primary amino group rather than a tertiary function as in many opiates is perhaps not surprising. Normorphine, which contains a secondary amino group, is as active as morphine in various *in vivo*[5] and *in vitro*[6] systems, thus showing that the presence of a tertiary amino group is not an absolute requirement for agonist activity. The importance of the phenolic hydroxyl group in opiate agonists and antagonists is well known[7,8], and results from various *in vitro* systems[3] show that the methyl ether of morphine, codeine, has only 0.7% of the potency of morphine in the guinea pig ileum and a mere 0.053% of its activity in the rat brain stereospecific binding assay, whereas as an analgesic in man it has about 8% of the activity of the parent drug. In the 6,7-benzomorphan series it has also been shown that replacement of the 2′ phenolic-OH by $-NO_2-NH_2$, Cl or F groups leads to less active agonists[9].

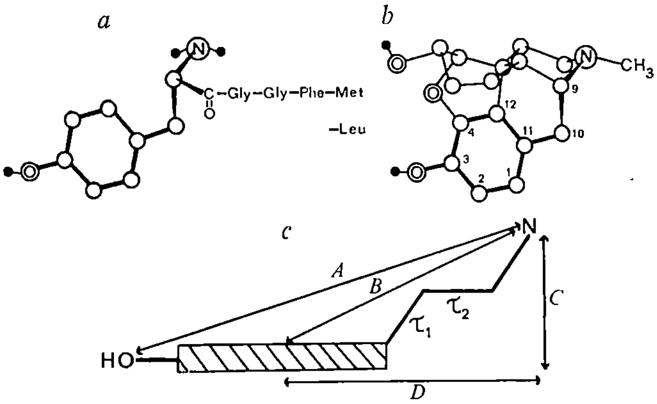

Fig. 1 *a*, Amino acid sequences of the enkephalin mixture[2] with the 'tyramine' moiety of the tyrosine residue in heavy outline. *b*, X-ray structure of (−)-morphine·HI (ref. 17) with the tyramine moiety in heavy outline. *c*, Diagrammatic presentation of a side-on view of the tyramine moiety, the rectangle representing the benzene ring. *A*, Distance of the nitrogen atom from the oxygen atom; *B*, distance of the nitrogen atom from the centre of the aromatic ring; *C*, perpendicular distance of the nitrogen atom above the plane of the benzene ring; *D*, distance of the centre of the aromatic ring from the point of intersection of the plane of the benzene ring and the perpendicular distance *C*. The torsion angle τ_1 is defined as the angle between the planes of the atoms C1–C11–C10 and C11–C10–C9, that is, for rotation about the C11–C10 bond. Torsion angle τ_2 is the angle between the planes of the atoms C11–C10–C9 and C10–C9–N, that is, for rotation about the C10–C9 bond.

Although there is a 2-carbon chain between the benzene ring and the nitrogen atom there are also two possible 3-carbon chains between these two functions in the morphine, morphinan and 6,7-benzomorphan analogues; but preparation of simple 3-carbon amines carrying a *m*-phenolic-OH group produced drugs with only very weak analgesic activity[10]. As well as having a similar molecular fragment, most opiates exhibit stereospecificity of action[7]; essentially all the analgesic activity resides in the (−)-isomer, and the configuration at C9 in (−)-morphine and at the equivalent carbon atoms in the active morphinans and 6,7-benzomorphans is the same[14].

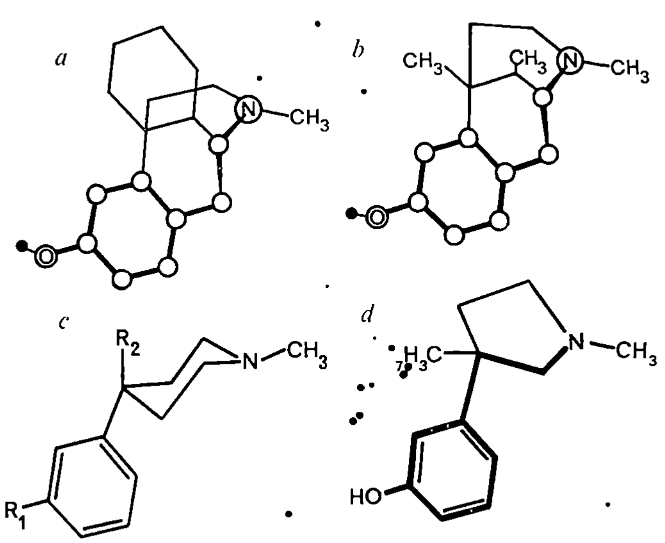

Fig. 2 The opiate agonists levorphanol (*a*) and metazocine (*b*) with the tyramine moiety in heavy outline; *c*, the 4-phenylpiperidines; *d*, profadol with the 2-carbon side chain amine and aromatic ring in heavy outline. ○, carbon atoms; ●, hydrogen atoms.

As the actions of the opiates are stereospecific and they are more or less rigid molecules, one possible way of obtaining information about the most likely opiate receptor conformation of the 'tyramine' portion of the tyrosine residue in the enkephalin pentapeptides is to examine the conformations of the tyramine residue in the potent opiates as determined by X-ray crystallography. The opiates are fairly rigid molecules so the conformation obtained from the X-ray data can confidently be assumed to be very similar to that occurring at the opiate receptor. We have therefore determined certain molecular parameters (Fig. 1*c* and Table 1) for the tyramine fragment in several conformationally restricted opiate agonists and antagonists based on published X-ray data. It is probably reasonable to examine both opiate agonists and antagonists, as there is now excellent evidence that they are combining with the same or very similar receptor sites[3,4,6,11,12]. For the agonists morphine and codeine, the antagonists, naloxone and 2-allyl 5,9-dimethyl-2′-hydroxy 6,7-benzomorphan[13] (*N*-allylnormetazocine) and the agonist–antagonist[6] cyclazocine (*N*-cyclopropylmethylnormetazocine) we find the following mean values for the various molecular parameters $A = 7.0$ Å, $B = 4.5$ Å, $C = 1.2$ Å, $D = 4.4$ Å $\tau_1 = 175°$ $\tau_2 = -89°$. A combination of some of these or closely similar values may correspond to the optimal opiate receptor site conformation for the 'tyramine' fragment of the enkephalins. Further simplifications of the morphine structure has led to molecules having greater degrees of conformational freedom, such as the 4-phenylpiperidines (Fig. 2*c*) and the 3-phenylpyrrolidines (Fig. 2*d*). The former group of drugs is

Table 1 Molecular parameters for various opiate agonists, antagonists and other drugs

	A(Å)	*B*(Å)	*C*(Å)	*D*(Å)	τ_1 (degrees)	τ_2 (degrees)
(−)-Morphine·HI[17]	7.08	4.55	0.81	4.47	164.7	−94.9

L-Tyrosine ethyl ester[24]	7.91	5.19	1.32	5.02	108.1	179.9

* The molecular parameters are defined in the legend to Fig. 1. Values *A*, *B*, *C*, τ_1 and τ_2 were all calculated from the published atomic coordinates; the values for *D* were obtained by simple geometry.

based on the piperidine–phenol ring fragment in morphine and it is, therefore, not surprising that the optimal position for the hydroxyl group is *meta* with respect to the piperidine ring[14]. The most active drugs of the 3-phenylpyrrolidine series also have the hydroxyl group in the *meta* position[15]. Although in the tyramine fragment of morphine the hydroxyl group is *para*, models of the 3-phenylpyrrolidines clearly show that the spatial disposition of the nitrogen atom with respect to the benzene ring and hydroxyl group is very similar to that in morphine.

Similar considerations apply to the *m* hydroxyl 4-phenylpiperidines although here models and the *B* distance in meperidine (Fig. 2*c*, $R_1 = H, R_2 = -\overset{\overset{O}{\|}}{C}-OC_2H_5$) indicate that the distances differ from those found for the more rigid opiates. Two of the more widely investigated drugs in this group are the agonists bemidone (Fig. 2*c*, $R_1 = OH$, $R_2 = -\overset{\overset{O}{\|}}{C}-OC_2H_5$) and (−)-profadol (Fig. 2*d*). In *in vitro*[3,6] systems the former has $^1/_{12}$ and the latter $^1/_9$ of the potency of (−)-morphine. It is therefore tempting to ascribe this decrease of potency to the greater degree of conformational mobility and to the fact that the various moieties may not be held in their optimal positions as in the more rigid opiates. This simple concept is complicated, however, by the fact that ketobemidone (Fig. 2*c*, $R_1 = OH$, $R_2 = -\overset{\overset{O}{\|}}{C}-C_2H_5$) both in *in vivo*[7,14] and *in vitro*[3] tests has a similar potency to morphine; the conformation of this drug, in the crystal state and in solution, is worthy of further study. Clearly however, with these less rigid drugs it is unwise to place too much importance on the possible pharmacological significance of values obtained by these methods.

It must be stressed, however, that although the presence of the tyramine fragment may be of importance in partially explaining the action of several groups of agonists and antagonists the stereospecificity/selectivity factor and the contribution of additional modes of binding from other portions of the molecule are obviously also critical[8]. The fact that drugs such as methadone and dextromoramide are quite different from those discussed here, and do not contain a tyramine fragment yet have agonist activities equal to or greater than morphine[7] and are probably acting on the same receptor[3,6,16], reinforces the above suggestions that other structural factors and modes of receptor interaction are obviously also important.

It is well known[7] that the introduction of certain substituents on to the N atom converts the opiates into antagonists, for example, substitution of an allyl group for the methyl group on nitrogen converts the agonists morphine and oxymorphone into the antagonists nalorphine and naloxone, respectively. It would be of interest to see what effect similar substitutions on the nitrogen of the tyramine fragment of the enkephalins produced, that is, would this result in antagonists or just less active molecules? Until there are data on the crystal and solution conformations of the enkephalins and the results of varying the structure are known, it would be premature to speculate on the significance of the rest of the peptide sequence. It seems worthy of emphasis, however, that the 'tyramine' conformation we have suggested might be the preferred one, for these pentapeptides at opiate receptors may not correspond to the preferred conformation for this residue found by X-ray crystallography, NMR spectroscopy or theoretical calculations, because the enkephalin pentapeptides are flexible molecules unlike the opiates and close analogues which are fairly rigid. In this regard, it is of interest that both tyramine HCl and tyrosine ethyl ester in the crystalline state have similar values for some of the molecular parameters (Table 1) but that these differ from those found for the opiates.

After this paper had been accepted for publication an article by Bradbury *et al.* appeared[25] in which they suggested that methionine enkephalin bears no similarity in its primary structure to the opiates; we feel, however, that our theory argues strongly against this.

Increased membrane fluidity implicated in acceleration of decay of post-tetanic potentiation by alcohols

AFTER repetitive stimulation of a synapse, the efficacy of synaptic transmission may be potentiated for a period. In systems that lend themselves to detailed analyses, this post-tetanic potentiation (PTP) has been shown to be due to an increased amount of transmitter released by the presynaptic neurone rather than to postsynaptic mechanisms[1]. We have investigated the PTP of a monosynaptic, all-or-none, excitatory postsynaptic potential (e.p.s.p.) recorded in cell R15 of the abdominal ganglion of *Aplysia californica* with appropriate stimulation of the right visceropleural connective, and have presented evidence that the PTP of this e.p.s.p. is based on increased transmitter release[2]. We have shown[3] that while PTP is slightly prolonged by lowering the temperature of the preparation from 20 to 12 °C, the duration of the PTP is increased tenfold by further lowering of the temperature to 10 °C This demonstration of a transition temperature suggested that the fluidity of critical lipids in the presynaptic membrane regulates the decay of PTP, such that PTP decays more slowly in conditions of decreased membrane fluidity. If this inference is correct, agents, such as alcohols[4], that increase membrane fluidity and thus act as 'antifreezes', should either prevent the occurrence of the temperature transition or lower the transition temperature. These agents should also, by themselves, accelerate the rate of PTP decay and their potency should be correlated with their lipophilicity. We present here experimental evidence in support of these predictions.

The abdominal ganglion of *A. californica* was pinned in a dish and perfused with fortified artificial seawater at 15 °C

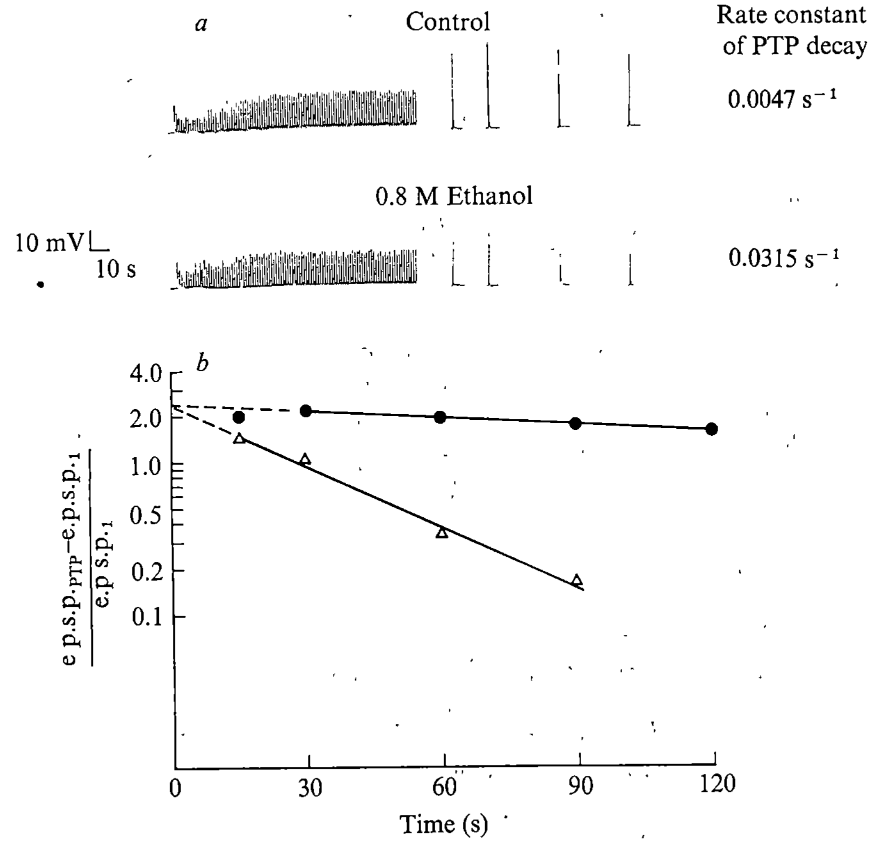

Fig. 1 Bath application of 0.8 M ethanol increases the rate constant of the decay of PTP. *a*, Intracellular record of the e.p.s.p.s recorded in cell R15 of the abdominal ganglion on stimulation of the right visceropleural connective during a train of 100 pulses at 1 per s followed by test pulses at 15-s intervals and then every 30 s. Cell R15 was hyperpolarised to −100 mV by injecting current through the second barrel of a double-barrelled recording electrode. Repetitive stimulation at 1 pulse per s resulted in an initial decrease in the size of the e.p.s.p. (synaptic depression) followed by a gradual increase of the e.p.s.p. amplitude to a facilitated plateau (frequency facilitation). When the train stopped, PTP of the e.p.s.p. amplitude was observed Thirty minutes after a control train ethanol perfusion was begun and a train was given in the presence of ethanol 30 min later. Ethanol had no effect on the amplitude of the e.p.s.p.s during the train but selectively shortened the duration of PTP. *b*, During PTP, the amplitude of the test e p.s.p. (e.p.s.p.$_{PTP}$) returned towards the size of the first e.p.s.p. of a train (e.p.s.p.$_1$) with a single exponential time course. The rate constant of the decay of PTP (the slope of the straight line fitted to the data points after the peak by linear regression analyses) was increased by the application of ethanol. The zero time intercept (a measure of the PTP amplitude) was not affected significantly by ethanol. Data are from a single preparation. ●, Control; △, 0.8 M ethanol.

(ref. 5) to which alcohols were added when indicated. Cell R15 was hyperpolarised to eliminate endogenous bursting; stimulation and intracellular recording were as before[2,5]. The right visceropleural connective was stimulated with trains of 100 pulses at 1 s^{-1}. On termination of the train, two test pulses were given at 15-s intervals to obtain an approximation of the maximal amplitude of the e.p.s.p. during the PTP period. Thereafter test pulses were given at 30-s intervals to obtain an estimate of the duration of PTP.

Perfusion of the preparation with 0.8 or 1.0 M ethanol (in fortified artificial seawater[5]) greatly accelerated the decay of PTP (Fig. 1 and Table 1). The effect on PTP decay was selective, since, on the average, ethanol had no effect on an isolated e.p.s.p., on synaptic depression (the ratio of the amplitudes of the first to the second of a pair of e.p.s.p.s 1 s apart), on frequency facilitation (the ratio of the last to the the first e.p.s.p. of a train) or on the maximum amplitude of the PTP (the zero time intercept of plots like that of Fig. 1*b*) (Table 1). Ethanol has also been seen to increase the rate of decay of PTP at a mammalian neuromuscular junction[1].

We tested the effect of ethanol on the transition temperature below which PTP decays very slowly[3]. In three different experiments, lowering the temperature from 20 °C to 8 °C, in the presence of 0.8 M ethanol, only slightly increased the duration of the PTP, and no evidence was found for the existence of a transition temperature between 12 °C and 10 °C. In each of these three preparations the ethanol was subsequently removed and the duration of the PTP was determined at 12 °C and 10 °C. In the absence of ethanol the PTP was strikingly prolonged on lowering the temperature from 12 °C to 10 °C as had been found before[3]. The fact that ethanol, an agent which promotes membrane fluidity[4], prevents the effect of lowering temperature, supports our conclusion[3] that the transition temperature reflects the sudden decrease in the fluidity of critical presynaptic membrane components.

The inference that ethanol accelerates the rate of decay of PTP by promoting membrane fluidity was further supported by the progressive increase in potency of the series of aliphatic alcohols (ethanol to *n*-octanol) in accelerating the decay of PTP (Fig. 2*a*) The relative potency of the alcohols correlated with their partition coefficient in an *n*-octanol–water system[6] (Fig. 2*b*).

These findings, that alcohols accelerate the decay of PTP, and prevent the previously observed[3] temperature transition in the rate of PTP decay, suggest that the rate is limited by the membrane fluidity of some nerve terminal component. How direct an effect membrane fluidity has on PTP decay rate is unknown. The effect could be fairly indirect. For example, increasing membrane fluidity may activate a membrane-bound enzyme which in turn promotes the decay of PTP. Alternatively, the change in efficiency of transmitter release which directly underlines PTP[2,7,8] may itself be a

Table 1 Effect of ethanol on an isolated e.p.s.p., synaptic depression, frequency facilitation and PTP

	Isolated e.p.s.p. (mV)	Synaptic depression	Frequency facilitation	PTP	Rate constant of decay of PTP (s^{-1})
Control ± s.e.	12.6±2.4	1.11±0.03	1.71±0.23	0.72±0 22	0.0038±0.0006
1.0 M ethanol ± s.e.	13 2±1.9	1.10±0.03	1.40±0.09	0.76±0.26	0.0245±0.0064
P (paired *t* test, $n = 11$)	NS	NS	NS	NS	<0.005

Synaptic depression is defined as the ratio of the amplitudes of the first to the second e.p s.p.s of a train elicited at a frequency of 1 s^{-1}. Frequency facilitation is the ratio of the amplitudes of the last to the first e.p.s.p. of a train of 100 pulses at 1 s^{-1}. To determine the amplitude of PTP and the rate constant of decay of PTP, the first four test e.p.s.p.s given at 30-s intervals starting 15 s after the end of a train were plotted as in Fig. 1*b*. A straight line was fitted to these points by linear regression analyses. The zero time intercept is a measure of the PTP amplitude and the slope of the line represents the rate constant of decay of PTP. NS, not significant.

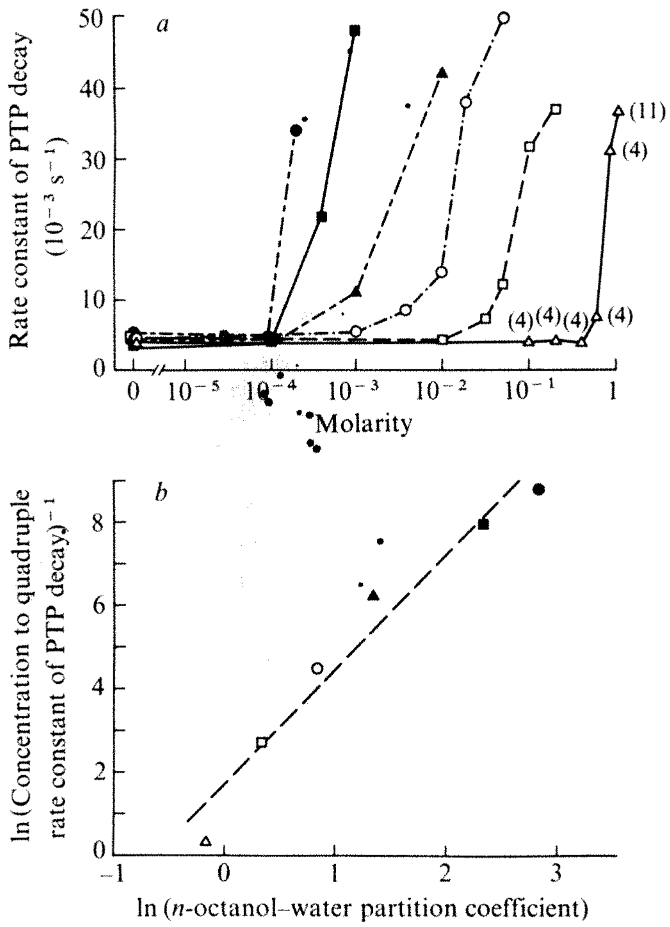

Fig. 2 *a*, Potency of aliphatic alcohols in increasing the rate constant of PTP decay. ●, C_8; ■, C_7; ▲, C_5; ○, C_4; □, C_3; △, C_2. The size of the carbon chain is indicated by the number (C_2 is ethanol; C_8 is *n*-octanol). An aliphatic alcohol (in fortified artificial seawater) was perfused for 30 min, beginning 30 min after a control train; and then a train was given in the presence of the alcohol. In contrast with ethanol, the higher alcohols reduced the amplitudes of all e.p.s.p.s. PTP still decayed, however, with a single exponential time course with a rate constant which was readily determined. Each data point represents the average value obtained from three different preparations, except for ethanol where the number of preparations at each data point is indicated. Note that the effect of each alcohol increases markedly over a narrow range of concentration. *b*, The potency of the effect of the different alcohols (measured as the concentration, *C*, needed to increase the rate of decay of PTP fourfold) correlates with the lipophilicity of the alcohol (as measured by the *n*-octanol : water partition coefficient, *P*). The data points were obtained from (*a*) by interpolating the concentration of each alcohol which would give a rate constant of PTP decay of 20×10^{-3} s^{-1}. A plot of $\ln(1/C)$ against $\ln P$ gives a straight line with the equation $\ln(1/C) = 2.71 \ln P + 1.66$. Other biological systems susceptible to alcohols similarly give straight lines in these coordinates[6]. Symbols as in (*a*).

change in presynaptic membrane organisation (for example, a change in the number or effectiveness of "vesicle attachment sites"[9]). In this latter case, the relaxation of this state of organisation would correspond to the decay of PTP, and would be directly affected by the fluidity of components of the presynaptic membrane. Evidence that this possibility is consistent with other known properties of PTP will be presented later. Regardless of the steps connecting membrane fluidity to the rate of PTP decay, our findings suggest that nerve terminal membrane fluidity is a potential physiological regulation point for the duration of PTP.

We thank Drs S. J. Singer and J. P. Tremblay for their comments and suggestions during the progress of this work, and Mr C. K. Becker for technical assistance. Single-channel currents recorded from membrane of denervated frog muscle fibres

THE ionic channel associated with the acetylcholine (ACh) receptor at the neuromuscular junction of skeletal muscle fibres is probably the best described channel in biological membranes. Nevertheless, the properties of individual channels are still unknown, as previous studies were concerned with average population properties. Macroscopic conductance fluctuations occurring in the presence of ACh were analysed to provide estimates for single channel conductance and mean open times[1–3]. The values obtained, however, depended on assumptions about the shape of the elementary conductance contribution—for example, that the elementary contribution is a square pulse-like event[2]. Clearly, it would be of great interest to refine techniques of conductance measurement in order to resolve discrete changes in conductance which are expected to occur when single channels open or close. This has not been possible so far because of excessive extraneous background noise. We report on a more sensitive method of conductance measurement, which, in appropriate conditions, reveals discrete changes in conductance that show many of the features that have been postulated for single ionic channels.

The key to the high resolution in the present experiments lies in limiting the membrane area from which current is measured to a small patch, and thereby decreasing background membrane noise. This is achieved by applying closely the tip of a glass pipette, 3–5 μm in diameter, on to the muscle surface, thus isolating electrically a small patch of membrane (Fig. 1). This method has been applied previously in various modifications and mostly with larger pipette tips to muscle[4], molluscan neurones[5,6], and squid axon[7]. The pipette, which has fire-polished edges, is filled with Ringer's solution and contains the cholinergic agonist at micromolar concentrations. Its interior is connected to the input of a virtual-ground circuit, which clamps the potential inside the pipette to ground and at the same time measures current flowing through the pipette, that is, through the patch of membrane covered by the pipette opening. The interior of the muscle fibre is clamped locally to a fixed value by a conventional two-microelectrode clamp[8]. Thus, voltage-clamp conditions are secured across the patch of membrane under investigation. Since current

densities involved are very small, a simple virtual ground inside the pipette is preferable to more complicated arrangements for stabilising potential described previously[6].

The dominant source of background noise in these measurements was the leakage shunt under the pipette rim between membrane and glass. It was constantly monitored by measuring the electrical conductance between pipette interior and bath. Discrete conductance changes could be resolved only when the conductance between pipette interior and bath decreased by a factor of four or more after contact between pipette and membrane. To minimise the leakage conductance, the muscle was treated with collagenase and protease[9]. This enzyme treatment digested connective tissue and the basement membrane, thereby enabling closer contact between glass and membrane. At the same time, however, it made the membrane fragile and more sensitive to damage by the approaching pipette. It did not, however, change the ACh sensitivity of the fibre or alter the properties of ACh-induced conductance fluctuations (E.N. and B.S., unpublished).

All experiments were carried out on the extrasynaptic region of denervated hypersensitive muscle fibres. The uniform ACh sensitivity found over most of the surface of these fibres greatly enhanced the probability of the occurrence of agonist-induced conductance changes at the membrane patch under investigation. Extrasynaptic ACh channels of denervated muscle fibres have mean open times which are about three to five times longer than those of endplate channels[1,10–12]. The longer duration facilitated the detection of conductance changes. Additional measures were taken which are known to either increase the size of the elementary current pulse or prolong its duration: the membrane was hyperpolarised up to −120 mV; suberyldicholine (SubCh) was used as an agonist in most of the experiments; the preparation was cooled to 6–8 °C.

Figure 2 shows a current recording taken in the conditions outlined above. Current can be seen to switch repeatedly between different levels. The discrete changes are interpreted as the result of opening and closing of individual channels. This interpretation is based on the very close similarity to single-channel recordings obtained in artificial membrane systems[13]. The preparation under study is, however, subject to a number of additional sources of artefact. Therefore it is necessary to prove that the recorded events do show the properties which are assigned to ionic channels of the cholinergic system. These are: a correlation with the degree of hypersensitivity of the muscle membrane; an amplitude dependent on membrane potential as predicted by noise analysis; a mean length or channel open time, which should depend on voltage in a characteristic manner[2]; pharmacological specificity with different mean open times for different cholinergic agonists[14,15]. The experiments bore out all of the above-mentioned points as outlined below.

The frequency of occurrence of single blips depended on the sensitivity of the patch under investigation. A plot of the number of current pulses per second against the iontophoretically measured sensitivity of the membrane region, determined either immediately before or after the pipette experiment, revealed a distinct correlation between both quantities with a correlation coefficient of 0.91 for a linear regression (Fig. 3*b*). Student's *t* test assigned a significance better than 0.1% to the relationship.

To estimate the size of the current pulses amplitude histograms were calculated from the current recordings (Fig. 3*c*). The histograms show a prominent peak of gaussian shape around zero deviation, the width of which is a measure of the high frequency background noise of the current trace. Multiple, equally spaced peaks at larger deviations represent the probabilities that either one, two, or three channels are open simultaneously. The peak separation gives the amplitude of the single-channel contribution, which was 3.4 pA for the histogram shown in Fig. 3*c*.

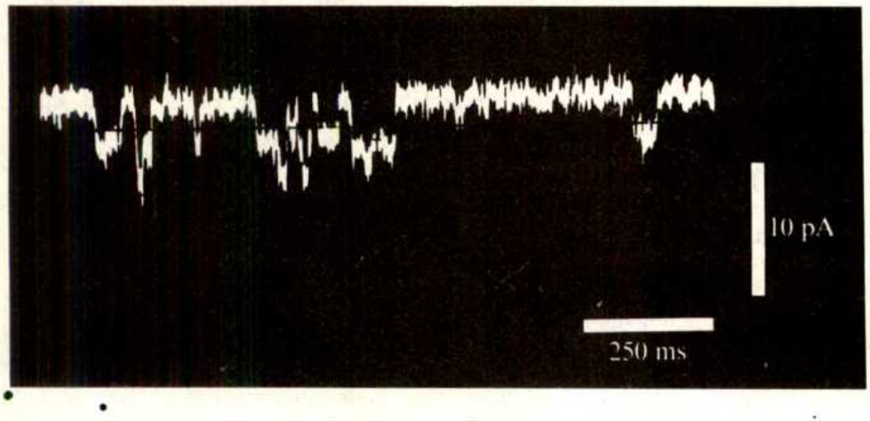

Fig. 2 Oscilloscope recording of current through a patch of membrane of approximately 10 μm². Downward deflection of the trace represents inward current. The pipette contained 2×10^{-7} M SubCh in Ringer's solution. The experiment was carried out with a denervated hypersensitive frog cutaneus pectoris (*Rana pipiens*) muscle in normal frog Ringer's solution. The record was filtered at a bandwidth of 200 Hz. Membrane potential: −120 mV. Temperature: 8 °C.

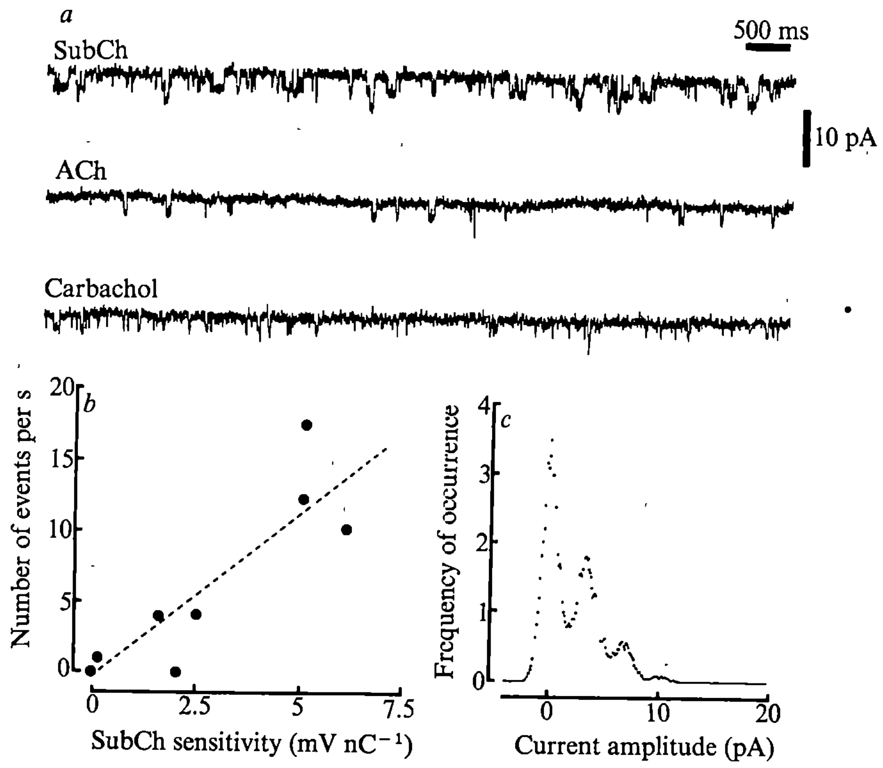

Fig. 3 Characterisation of single-channel currents. *a*, Comparison of current recordings obtained with different cholinergic agonists at concentrations of 2.10^{-7} M(SubCh), 2.10^{-6} M(ACh), and 6.10^{-5} M(carbachol). Downward deflection of the trace represents inward current. Three different experiments. Pen records replayed from analogue tape at a bandwidth of 100 Hz. All experiments at −120 mV membrane potential; 8 °C. *b*, Number of current blips per second is plotted against iontophoretic sensitivity of the membrane region under investigation. Sensitivity was determined by 100-ms iontophoretic pulses delivered from a pipette filled with 1 M SubCh (40 MΩ pipette resistance, 10 nA bucking current, sensitivity measured at resting potential). Pooled data from eight experiments. Broken line represents linear regression. *c*, Amplitude histogram of membrane current. Current traces were digitalised and baselines fitted by eye to data records, each 4 s in length. Frequency of occurrence of deviations from the baseline is shown in arbitrary units. Histograms were calculated on a PDP-11 computer; 2–8 histograms were averaged to obtain curves like the one shown. 8 °C; −120 mV membrane potential.

This was obtained from an experiment at −120 mV membrane potential. A similar histogram from the same muscle fibre obtained at −80 mV yields a current pulse amplitude of 2.2 pA. These two values extrapolate to an equilibrium potential of −7 mV. Channel conductance is estimated as 28 pmhos in this case. It scattered from fibre to fibre with a mean value of 22.4±0.3 pmhos (mean±s.e.; number of determinations=27). This value is somewhat lower than the one derived from noise analysis at normal endplates, which is 28.6 pmhos for SubCh[15]. Higher order peaks in the histograms are not merely scaled images of the zero order peak. They tend to be smeared out due to non-uniformity of current pulse amplitudes. We cannot decide at present whether this is a real feature of the channels or a measurement artefact. Such an effect could arise if not all of the channels are located ideally in the central region of the pipette opening. Current contributions from peripherally located channels would only partially be picked up by the pipette. This source of error is also likely to lead to an underestimate of channel size if the pipette seal is not optimal.

Temporal analysis of the current records was carried out partly by measurement of individual channel length and averaging 40–50 measurements, and partly by calculation of the power spectrum of the current recordings. In the latter case, the cutoff frequency f_0 of the Lorentzian spectrum yielded an estimate of mean channel open time τ (or pulse duration) through the relationship $\tau=1/(2\pi f_0)$. Values of mean open times obtained by the two methods were consistent within ± 30%. For SubCh as an agonist and at a temperature of 8 °C it was 45±3 ms (n=11) at −120 mV and 28±3 ms (n=14) at −80 mV. These values are approximately three times longer than the corresponding mean open times of endplate channels derived from noise analysis[15]. Note, however, that lengthening of channel durations by factors of three to five at extrajunctional sites with respect to endplate values has been measured independently by conventional noise analysis[12]. The voltage dependence of the values given above corresponds to an *e*-fold change per 80 mV, which is within the range of published values[2].

Channel open times were different when different cholinergic agonists were used (Fig. 3*a*). For −120 mV and 8 °C, mean channel open time was 45±3 ms (n=11) for SubCh, 26±5 ms (n=4) for Ach, and 11±2 ms (n=3) for carbachol. This sequence reflects the well known relationship between the open times of channels induced by these drugs at normal endplates[14,15] and at extrasynaptic membrane of hypersensitive fibres[12].

The results obtained so far, especially the pharmacological specificity, lead us to conclude that the observed conductance changes are indeed recordings of single-channel currents. They are consistent with the conclusions drawn from statistical analysis of endplate current fluctuations, and show that current contributions of individual channels are of the form of square pulses. In addition, analysis of areas under the peaks of histograms like Fig. 3*c* indicates that in our experimental conditions opening of individual channels is statistically independent, since the probabilities of zero, one, or two channels being open simultaneously follow—within the limits of experimental resolution—a Poisson distribution.

Recordings of single-channel currents finally resolves the third level of quantification in the process of neuromuscular transmission after the discovery of endplate currents and miniature endplate currents. It should facilitate discrimination between factors influencing the properties of single channels and agents creating or modifying different populations of channels.

We thank J. H. Steinbach for help with some experiments. Supported by a USPHS grant to Dr C. F. Stevens, and a stipend of the Max-Planck-Gesellschaft.

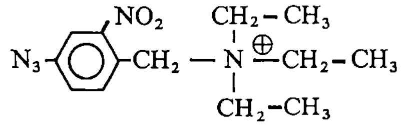
Selective inhibition of potassium conductance in node of Ranvier with a photoaffinity label derived from tetraethylammonium

BIOCHEMICAL investigation of membrane components involved in ion-specific conductance changes is difficult because of the lack of a functional assay for the components after membrane solubilisation. Proteins thought to participate in conductivity changes during synaptic transmission[1] have been isolated using a binding assay and affinity chromatography[2,3], because of their high affinity for a variety of ligands; but the connection between such receptor proteins and postulated ion channels remains to be shown. To isolate molecules forming sodium channels of the axon membrane[4–7], tetrodotoxin was used as ligand (binding assay $K_d = 3$ nM). The most efficient known blocking agent of the change in potassium conductance in nerve and muscle known is tetraethylammonium (TEA) but its affinity is too low ($K_d = 0.4$ mM (ref. 8)) for either of the above techniques. We have attempted to label radioactively those molecules associated with the voltage-dependent potassium conductance changes covalently *in situ* with the aim of recovering that radioactivity after solubilisation using classical fractionation procedures. We suggest that it is possible to block selectively and irreversibly potassium conductance in myelinated nerve fibres using a photoaffinity lable. This method may open the way for the isolation of the TEA receptor of excitable membranes, proposed as part of the potassium channel (if not the channel itself).

We applied 4-azido-2-nitrobenzyltriethylammonium fluoroborate,



$$N_3\text{-}C_6H_3(NO_2)\text{-}CH_2-\overset{\oplus}{N}(CH_2\text{-}CH_3)_3$$

which belongs to a class of photoaffinity labels developed by H.K.[9] and which was first used in the investigation of the structure of the acetylcholine receptor (F.H., P. Layer, H.K. and G. Bandini, unpublished) and the acetylcholine esterase (P. Layer, H.K. and F.H., unpublished). The label was synthesised using the same procedure described for the corresponding trimethylammonium derivative (P. Layer, H.K. and F.H., unpublished). Voltage clamp experiments were carried out with sensory and motor fibres of the sciatic nerve of the frog *Rana esculenta*[10,11]. The Ranvier node was continuously superfused with Ringer or the test solution as indicated in Figs 1–4. Photoaffinity labelling was induced by irradiation with an ultraviolet lamp Typ TL-900 (Camag, Switzerland; emission maximum 254 nm; lamp distance from fibre 5 cm). Without irradiation the photoaffinity label reversibly inhibited the potassium conductance (Fig. 1*c*), whereas the sodium conductance was not affected.

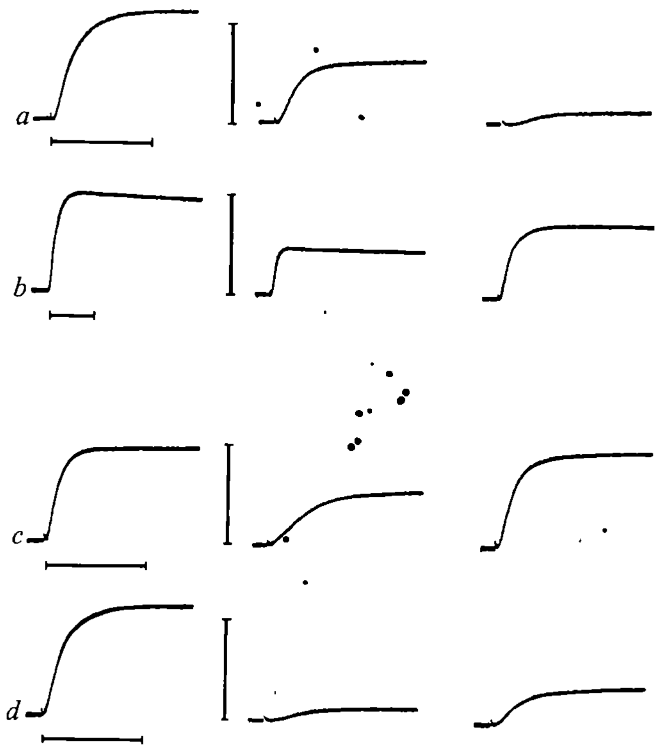


Fig. 1 Potassium current records during 140 mV depolarising pulses from a holding potential of −100 mV. Capacity and leakage currents were compensated analogically. Test node superfused with Ringer's solution (117 mM NaCl, 2.5 mM KCl, 1.8 mM $CaCl_2$) plus tetrodotoxin (300 nM). Control, First record in each row. In each experiment photoaffinity label (1 mM) was added either to Ringer's solution (*a*, *c* and *d*) or to isosmotic KCl solution in contact with the cut ends of the fibre (*b*). *a* and *b*, Effects of photoaffinity label applied either externally (*a*) or internally (*b*), before (second records) or after (third records) application of ultraviolet light for 3 min. *c* and *d*, Reversibility for the experiment without (*c*) or with irradiation (*d*). Third record in *c* and *d* was taken 40 min after removal of photoaffinity label from Ringer's solution. Vertical and horizontal calibrations: 10 nA and 10 ms, respectively.

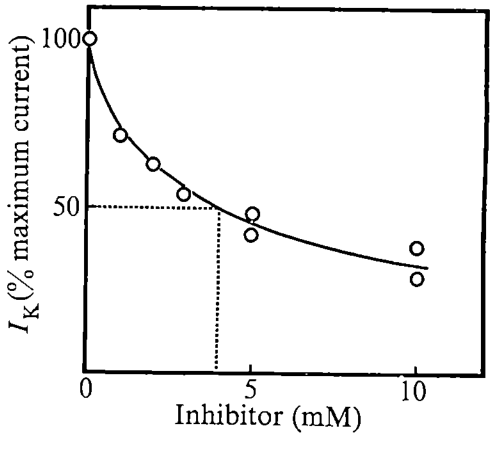
50% inhibition of the potassium current was obtained with 4 mM photoaffinity label (Fig. 2), indicating a much lower affinity than that for TEA ($K_d = 0.4$ mM (ref. 8)). During irradiation in the presence of the label the potassium current decreased markedly and rapidly (Figs 1*a* and 3), whereas the sodium current decreased only slightly (Fig. 3). In a typical experiment, we obtained after about 2 min irradiation an 80% decrease in potassium current and a less than 10% decrease in sodium current. After removal of the

Fig. 2 Dose–response curve for 4-azido-2-nitrobenzyltriethylammonium fluoroborate (without irradiation). Photoaffinity label was added to Ringer's solution used to superfuse test node. Temperature: 11 °C.



light source and washing the fibre with Ringer's solution, about 65% irreversible inhibition of the potassium current remained (Fig. 1*d*). Control experiments suggested that this irreversible inhibition arises by a photoreaction of the molecules bound to a receptor in the potassium channels and not from the action of photolytic products of the reagent. A solution irradiated before its application to the test node strongly inhibited the potassium conductance, but this inhibition was completely reversible. Exposing the test node to ultraviolet light in the absence of photoaffinity label showed that in our experimental conditions ultraviolet light alone had practically no effect on potassium conductance but a small effect on sodium conductance (Fig. 3*b*). These observations are in perfect agreement with similar observations by Fox[12].

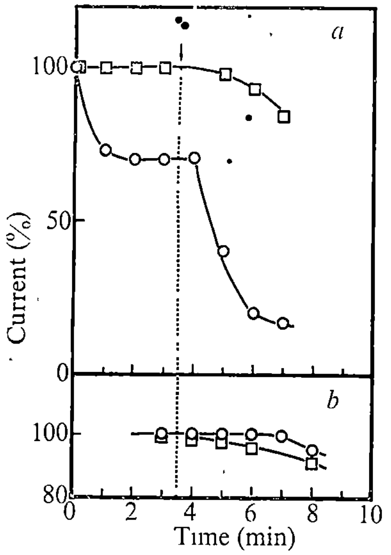


Fig. 3 Effects of photoaffinity label (*a*) and ultraviolet light (arrow) in the absence of photoaffinity label (*b*) on sodium (□) and potassium (○) currents. Ringer's solution with 1 mM photoaffinity label was applied 3.5 min before irradiation. The small effect observed on the sodium system may be explained in terms of the effects of ultraviolet light *per se* in the absence of photoaffinity label. Temperature 11 °C.

Photoaffinity label applied by diffusion from the cut ends of the fibre to the internal side of the nodal membrane caused, without irradiation, a similar selective inhibition of the potassium conductance (Fig. 1*b*). Surprisingly, irradiation with ultraviolet light had in this case the opposite effect to that in the case of external application of photoaffinity label (Fig. 1*b*). Instead of a further decrease there was an increase in potassium current, indicating that the binding site for the quaternary ammonium group is situated close to the internal opening of the potassium channel. According to this model, during irradiation in the case of application from the internal side of the axon, the 'reactive tail' of the photoaffinity label can react only with sites outside the channel—for example, with proteins from the axoplasm, the latter thereby being removed from the channel. When applied from the external side the label enters the channel far enough for a covalent attachment to sites inside the channel.

Analysis of the kinetics of potassium conductance activation after step depolarisation in the presence of photoaffinity label revealed a further difference between the internal and external site of the axonal membrane. When applied from the outside, without irradiation, the increase in potassium conductance was much slower compared with the control (Fig. 4*a*). After application from the inside the increase in potassium conductance was faster, and irradiation reduced it again to its original value (Fig. 4*b*). After the rapid increase in potassium conductance with some fibres a small inactivation of the potassium current was observed. This result is in agreement with experiments described by Armstrong[13,14], who observed an inactivation with internally applied benzyltriethylammonium and similar TEA derivatives.

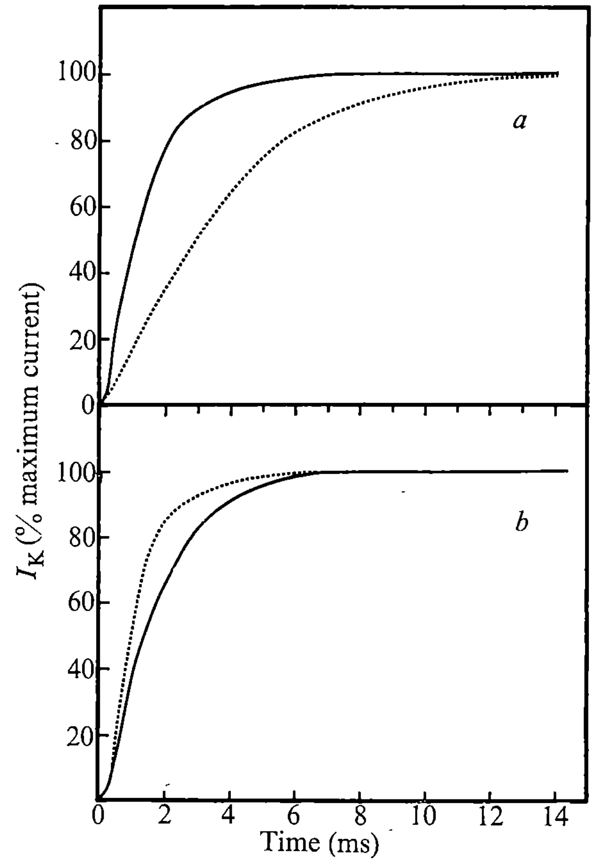

Fig. 4 Relative potassium current in the absence (solid line) or presence (dashed line) of photoaffinity label applied internally (*b*) or externally (*a*) without irradiation. *a*, 4 mM; *b*, 6.6 mM. Temperature, 11 °C.

One clear advantage of using our photoaffinity label is that its synthesis is straightforward, thus permitting radioactive labelling. Radioactive 4-azido-2-nitrobenzyltriethylammonium fluoroborate could be an important tracer for receptors associated with potassium channels.

α Foetoprotein and serum albumin show sequence homology

α FOETOPROTEIN (AFP) is a major plasma protein of the foetus[1], where it is produced by the yolk sac and the liver[2]. In adults its concentration is extremely low[3] except in patients with tumours such as hepatomas and teratomas[4,5]. AFP has a molecular weight of 70,000, consists of a single polypeptide chain and contains about 4% carbohydrate[6]. The similarity of the chemical properties of AFP and albumin and the fact that their concentrations in the serum are high and inversely related[7] has led to the suggestion[8] that AFP may be a foetal counterpart of albumin. We have determined amino acid sequences of fragments of human AFP and found homology between these and the albumin sequence.

Human AFP was purified using immunoadsorbents[9]. The purity of AFP was checked with gel electrophoresis and immunological tests. The preparations used did not react with anti-normal human serum (Behringwerke) in immunodiffusion when tested at a concentration of 5 mg ml^{-1}. The procedures used and characterisation of the AFP preparations have been described in detail[5,9]. AFP was reduced, alkylated with iodoacetamide and cleaved with cyanogen bromide[10] Peptides resulting from the cleavage were separated on Sephadex G-100 (Pharmacia) equilibriated with 6 M urea and ·1 M propionic acid. Sequence determination was carried out on an automatic sequencer (Beckman, Model 890). The phenylthiohydantoin (PTH) amino acids were identified with gas chromatography and amino acid analysis following hydrolysis back to amino acids both in hydrochloric acid and hydroiodic acid.

Cyanogen bromide cleaves AFP to seven peptides detectable by gel electrophoresis. Their molecular weights are 23,000, 12,000, 9,000, 8,000, 6,500, 4,000 and 3,500 (ref. 11). The 23,000 (I) and 12,000 peptides (II) were purified and their N-terminal sequences determined. Comparison of these sequences with the albumin sequence[12–15] revealed significant homology between the AFP fragments and certain parts of the albumin molecule (Table 1) The percentage of same-sequence positions between the two peptides and human and bovine albumin was 37–45. Computer search for homology between the AFP fragments and known protein sequences[16] revealed no further significantly homologous sequences and clearly established the significance of the similarity with albumin (Table 2).

These sequence data clearly indicate that AFP and albumin have a common ancestor This is in line with their general similarity. Their chemical properties differ markedly only with respect to carbohydrate content. Albumin does not contain carbohydrate, whereas AFP is a glycoprotein[6].

Our data do not permit accurate estimation of the degree of homology between AFP and albumin. The comparison is based only on 59 residues (out of about 600). Furthermore, the N-terminal sequences of albumin[17] and AFP[18] do not show homology. This may be due to insertion of additional

*Computer analysis carried out at the National Biomedical Research Foundation using existing sequence information[16]. The analysis compares the sequences of the AFP fragments with sequence fragments of corresponding length that are contained in the known sequences of 732 other proteins. The columns under peptides I and II indicate the number of sequence fragments with a given degree of similarity with the AFP fragments. This is expressed as the number of identical residue positions (=score) between the AFP sequence and the sequence with which it is compared.

sequence to the N-terminal of AFP or a deletion or post-synthetic modification in albumin. The fact that the pieces in the albumin sequence homologous with the relatively large AFP peptides are separated only by 30 amino acids, suggests rearrangement of these pieces in either one of the molecules.

Albumin binds a wide variety of different substances including fatty acids, drugs, and dyes[19]. AFP has been shown to bind certain hormones[20] and various dyes[21].

These similarities and the sequence homology suggest that albumin and AFP have similar functions as general carriers in plasma and perhaps in the maintenance of the osmotic pressure. In addition, AFP probably has special functions offering an advantage over albumin to the foetus. This may be connected with immunosuppression[22].

A detailed report on these results and further chemical characterisation of AFP will appear elsewhere.

Quantitative adaptation of isoacceptor tRNAs to mRNA codons of alanine, glycine and serine

THE optimum efficiency of protein biosynthesis depends on the availability of aminoacyl-transfer RNAs (tRNAs) in the neighbourhood of active polysomes, among other factors The intracellular tRNA level is directly proportional to the composition of the amino acids incorporated into proteins being synthesised[1]. This continuous and selective adjustment takes place in prokaryotes and eukaryotes and in non-differentiated as well as in highly specialised cell systems[2]. We report here that such a proportionality takes place at the molecular level between the frequency of synonomous codons in messenger RNAs (mRNAs) and the distribution of the corresponding isoacceptor tRNAs. A correlation was found for the alanine, glycine and serine codons from viral nucleic acids and eukaroytic iso-tRNA sets fractionated on reversed-phase chromatography as well as for the preponderant tRNAs involved in the translation of fibroin mRNA in the posterior silk gland of the silkworm *Bombyx mori* L.

The overall ratio of different tRNAs must include a relationship between the frequency of synonymous codons in mRNAs being decoded and the respective set of iso-tRNA species. To verify this relationship, the distribution of synonymous codons for the predominant amino acids in mRNA and the anticodon distribution of the corresponding isoacceptor tRNAs must be known. The former can be obtained from a statistical study of a large number of mRNAs of known sequence in normal tissue or from the structural analysis of the main mRNA of a specialised tissue, whereas the latter is obtainable from the codon response of fractionated tRNA species and from sequences.

In this study the average frequency of synonymous codons in viral RNAs of which the sequence is partially or completely known is compared with the average distribution of the respective iso-tRNA species in several eukaryotes. According to the general analysis of Grantham[3] with coliphage RNAs, the distribution of frequencies for degenerate codon positions is far from random. We assume that the same distribution frequency occurs in mRNAs from

Table 1 Average distribution of iso-tRNAs from eukaryotes and frequency of synonymous codons for alanine, glycine and serine in viral RNAs and DNA

	Codon response of iso-tRNA	Mean value±s.d. (%)	Viral codons (%)	
	U		32	
Alanine	GCC	73.4±4.6	21	82
	A		29	
	GCG	26.6±4.6	18	18
	U		58	
Glycine	GG	65.8±1.9		79
	C		21	
	A		9	
	GG	34.2±1.9		21
	G		12	
	U		8	
Serine	AG	32.3±5.4		20
	C		12	
	U		26	
	UCC	56.3±2.4	14	57
	A		17	
	UCG	11.4±4.3	23	23

The proportions of iso-tRNA species are taken from mean values calculated from 15 independent elution profiles on reversed-phase chromatography for different eukaryotic cells. The codon response of each peak was measured by ribosome binding and the distribution obtained from the elution profile (for tRNA$^{\mathrm{Ala}}$, see refs 4 and 5; for tRNA$^{\mathrm{Gly}}$, ref. 4; and for tRNA$^{\mathrm{Ser}}$, refs 4, 6 and 7). For iso-tRNA$^{\mathrm{Ala}}$ species chromatographic data are provided from *Drosophila*[8], rat liver[9], rabbit liver[10], rabbit reticulocyte[11], calf muscle[12], human lymphoblasts[13] and brain[10]. The minor iso-tRNA$^{\mathrm{Ala}}$ species not only decodes GCG, but also GCA; it seems to be a mixture of a third species recognising GCU and GCC in yeast[5], as in prokaryotic organisms. A similar situation exists in the silkgland of *B. mori* L.[31]. For iso-tRNA$^{\mathrm{Gly}}$ species data were obtained from *Drosophila*[8], rat liver[9], rabbit reticulocyte[11], calf muscle and lens[12]. For iso-tRNA$^{\mathrm{Ser}}$ species data come from *Drosophila*[8], rat liver (refs 7 and 14, and H. Rogg, unpublished), rabbit liver[10], rabbit reticulocytes[11], hen liver[15], human lymphoblasts[13], rat adrenal cortex, glioblastoma C-6 (H. Rogg, unpublished) and beef brain[7]. The frequency of alternative codons in partially and completely sequenced viral RNAs was determined from structural data compiled by Barrell and Clark[16]. Additional data were kindly provided by Fiers before publication of the total sequence of bacteriophage MS2 RNA coding for the A protein[17] and the partial 3′-end sequence of MS2 RNA coding for viral RNA polymerase[18], and by Guilley[19] for the partial sequence of RNA from the tobacco mosaic virus coat protein cistron. Of 980 analysed codons, 35 comes from f2 RNA, 678 from MS2 (393 from A protein, 129 for coat protein and 156 for replicase), 32 from Qβ, 91 from R17 and 77 from TMV. We have also taken into account 67 codons from the G gene coding for spike protein of φX174 DNA[20]. The sampling for alanine, glycine and serine are respectively 82, 48 and 89.

Table 2 Distribution of iso-tRNAs, amino acid–tRNA ligases and codons for alanine, glycine and serine in the posterior silk gland of *B. mori* L. on day 8 of the fifth instar

	Alanine			Glycine			Serine			Refs
Amino acids of fibroin (%)	29			46			12			22

Codons of fibroin mRNA (%)			29	27		19		12		—

*Presumed anticodon in parentheses.

†Estimated content according to the oligoribonucleotides analysis carried out by Suzuki and Brown[23] and to the amino acid composition of fibroin[22]. For calculating the linear correlation coefficient, we have taken both $tRNA^{Ala}$ species able to recognise GCU codon.

highly differentiated organisms The three tRNAs studied correspond to three main amino acids (alanine, glycine and serine) which account for 24±1% of the residues in common protein. The base in the 5′ position of the anticodon of their respective iso-tRNAs can be of four different kinds· inosine can recognise $XY\overset{U}{\underset{A}{C}}$ codons in $tRNA^{Ala}$ and $tRNA^{Ser}$, guanosine recognises $XY\genfrac{}{}{0pt}{}{U}{C}$ for $tRNA^{Ala}$, $tRNA^{Gly}$ and $tRNA^{Ser}$, uridine decodes $GX\genfrac{}{}{0pt}{}{A}{G}$ in $tRNA^{Ala}$ and $tRNA^{Gly}$ and cytidine UCG in $tRNA^{Ser}$ (see ref. 4 for review).

Table 1 shows the results of a statistical analysis of the composition of three iso-tRNA sets from 15 eukaryotic cell types after fractionation by reversed-phase chromatography. We have only retained the quantitative variations of the concentration of each isoaccepting species and *a priori* ruled out qualitative or structural modifications detectable with this type of chromatography. In spite of differences in resolution and some inversions in elution order due to experimental conditions, the variability in the number and proportion of the iso-tRNA species is small. It is thus possible to assign average values.

Table 1 also shows the frequency of synonymous codons for alanine, glycine and serine, which represent 22.4% of 980 codons analysed from viral RNAs and DNA φX174. Their distribution is non-random: XYU predominates. The correlation between the distribution of codons and the intracellular levels of the respective isoaccepting species corresponding to these codons is highly significant ($r = 0.93$).

It is also possible to correlate the iso-tRNA levels and codons frequency of a predominant mRNA in a specialised tissue such as the posterior silk gland of *B. mori* L The exponential accumulation of fibroin mRNA ($mRNA_F$) during the last larval instar up to 3.5% at the sixth day[21] leads to a massive biosynthesis of fibroin accounting for at least 75% of the proteins synthesised at the end of the secretion phase. Alanine, glycine and serine represents 87% of the total amino acids of fibroin[22]. Isolation and partial structural analysis of the 3′-exoguanylic oligoribonucleotides of $mRNA_F$ enabled Suzuki and Brown[23] to deduce the main codons for fibroin: GCU for alanine, GGU and GGA for glycine in a 1.4 : 1 ratio and UCA for serine. The distribution of glycine codons is markedly different from that in viral nucleic acids, for which the GGU : GGA ratio is 6 5 (Table 1). This distribution is sufficiently different to stimulate a distinctive composition of iso-$tRNA^{Gly}$ species in the posterior silk gland.

Several studies of the fibroin translational apparatus provide information about the intracellular levels of tRNAs during the fifth instar[24–28]. their cognate ligases[28–29], the changes of iso-tRNA species[27,30] and the nature of their anticodons determined either by response to codons[31] and to polynucleotides[32,33]; or directly analysed by sequencing; or by their modified nucleoside content (J.-P. Garel, unpublished). Table 2 clearly shows that the posterior silkgland iso-tRNAs match the peculiar distribution of their cognate codons in fibroin mRNA. ($r = 0.99$). Note that the ratio between the two main iso-$tRNA^{Gly}$ species (1.33) is different from that generally found (1.92, see Table 1).

The quantitative adaptation of iso-tRNA population to codon frequency of active mRNAs strongly suggests a coordinated regulation between the codon requirements of mRNA and the corresponding aminoacyl-tRNA species.

I thank W. Fiers, R. Grantham, D. Hentzen, J. Ofengand and H. Rogg for assistance.

Bifurcated hydrogen bonds and flip–flop conformation in a modified nucleic acid base, gc^{6}Ade

FROM an analysis of X-ray diffraction data on modified bases of transfer RNA (tRNA) and their ribonucleosides, we have established that these molecules can be made to undergo, by suitable changes in *p*H, a reversible flip–flop conformational change from one stable state to another across a high potential barrier. We have also shown that positive charges adjacent to C–H bonds in the heterocyclic ring of nucleic acid bases polarise these bonds and enable them to take part in strong hydrogen bonds to appropriate acceptors.

The modified nucleoside *N*^{6}-(*N*-glycylcarbonyl)adenosine (g^{6}A), previously termed *N*-(purin-6-ylcarbamoyl)glycine ribonucleoside[1], is an analogue of *N*^{6}-(*N*-threonylcarbonyl) adenosine (t^{6}A), and has been isolated[2] from enzyme digests of unfractionated yeast tRNA. We have carried out X-ray crystallographic studies of these anticodon-adjacent hypermodified bases at or near acidic (*p*H ~ 0) and alkaline (~ 8.0) *p*H, and of their ribonucleosides at *p*H ~ 3.5. At alkaline *p*H tc^{6}Ade and gc^{6}Ade bases are anions and these were crystallised (*p*H ~ 8.0) and studied by us as the corresponding potassium salts. The molecular structure of the gc^{6}Ade anion as obtained from the crystal structure[3] of (gc^{6}Ade)$^-$K$^+$ displays two important features (Fig. 1); the base takes up the 'distal conformation'[4] and an intramolecular hydrogen bond is formed from the hydrogen on N(glycine) to the N(1) of adenine. These two features are found in the structure of (tc^{6}Ade)$^-$K$^+$.4H$_2$O (ref. 4) and also in the structures of the uncharged ribonucleosides t^{6}A (ref. 5) and g^{6}A (R.P., and G.B.C., unpublished). We discuss here the chemical implications of these two conformational features; their biological role has been suggested elsewhere[4–6].

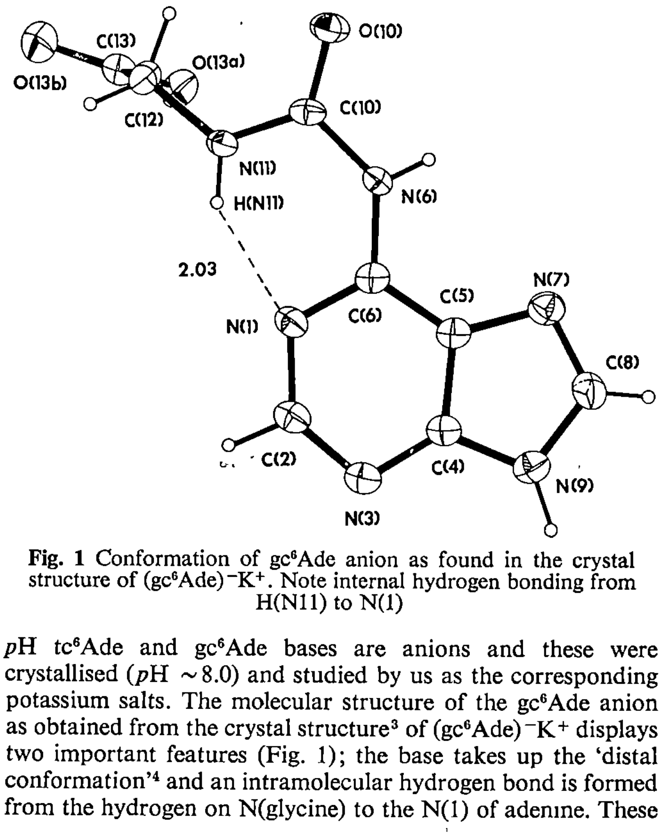

Fig. 1 Conformation of gc^{6}Ade anion as found in the crystal structure of (gc^{6}Ade)$^-$K$^+$. Note internal hydrogen bonding from H(N11) to N(1)

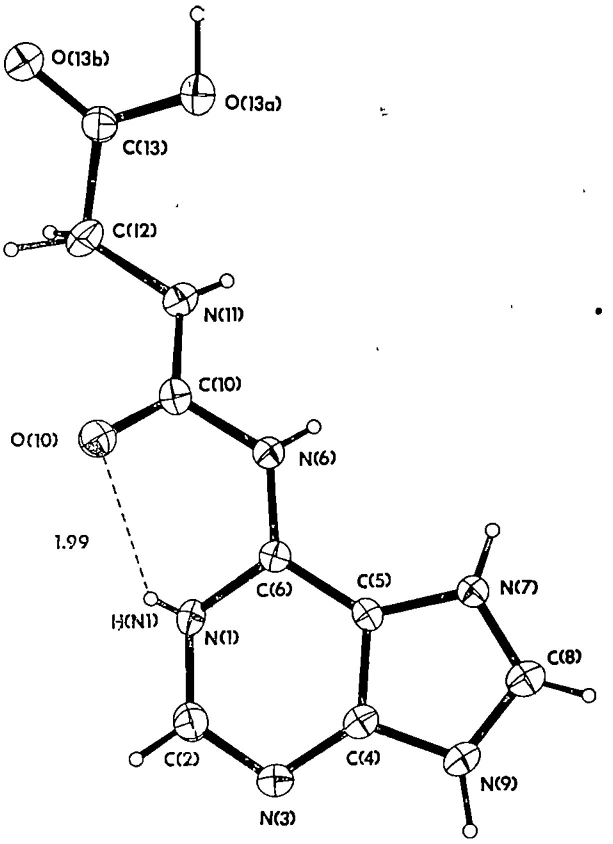

Fig. 2 Conformation of gc^{6}Ade dication as found in the crystal structure of (gc^{6}Ade)$^{2+}$ (2Cl)$^{2-}$. The protonation on N(1) has caused a change of conformation about the N(6)–C(10) bond giving rise to a different internal hydrogen bond, N(1)–H(N1) ··· O(10).

At acidic *p*H, the site of protonation for purine is N(1) although it has been argued[6] that it is N(7) or N(9). Monoprotonated adenine derivatives such as adenine hydrochloride hemihydrate[7], 3′-AMP (ref. 8), and 6-methyladenine hydrochloride[9], all show protonation on N(1). In gc^{6}Ade, N(1) is intramolecularly hydrogen bonded to H(N11) (Fig. 1); furthermore, the atoms N(11) and H(11) are held in this orientation by a series of conjugated covalent bonds, and are not free to move away from N(1). Consequently, it was of interest to determine in what conditions N(1) of gc^{6}Ade can be protonated. We therefore treated gc^{6}Ade with an excess of concentrated HCl solution to obtain crystals of the dihydrochloride derivative

Table 1 Table of bifurcated hydrogen bonds and weaker hydrogen interactions

D–H ··· A$_1$*	H ··· A$_1$	D ··· A$_1$	D–H ··· A$_1$	A$_1$ ··· H ··· A$_2$
D–H ··· A$_2$	H ··· A$_2$	D ··· A$_1$	D–H ··· A$_2$	(sum)†
N(1)–H(N1) ··· O(10)	1.99 Å‡	2.616 Å	132.1°	91.8°
N(1)–H(N1) ··· Cl(2$^{\text{i}}$)	2.49‡	3.141	136.1	360

‡Considered as hydrogen bonds; the other contacts are considered as weaker hydrogen interactions.

of gc^{6}Ade. These crystals are monoclinic, space group $P2_1/c$ with unit cell parameters: $a = 13.069(3)$ Å, $b = 9.878(1)$ Å, $c = 12.866(4)$ Å, $\beta = 134.27(1)°$, $D_{obs} = 1.65$ g cm^{-3}, D_{calc} (for $C_8H_{10}N_6O_3Cl_2$) = 1.62 g cm^{-3}, $Z = 4$, temperature = 22±3 °C, λ(CuKα) = 1.54051 Å. Using diffractometer data (2,582 reflections to the limit $2\theta = 160°$ for CuKα) the crystal structure was solved, and refined by the least-squares method to $R = 0.056$. Detailed correction for absorption was carried out. The hydrogen atoms were located from electron-density difference maps and their parameters refined by the least-squares method.

The structure analysis shows (Fig. 2) that the molecule is a dication with protonation on both N(1) and N(7) or N(9). Concomitant with the protonation is a change in the conformation of the molecule, a *cis–trans* isomerisation across the N(6)–C(10) bond stabilised by the formation of an intramolecular hydrogen bond N(1)–H(1) · · · O(10). Thus, the change in *p*H to the acidic side 'flipped' the molecule from one stable conformation to another stable one across a high potential barrier; the original conformation can be restored by increasing the *p*H. The basic pK_a of gc^{6}Ade measured by us is 2.6, compared with a pK_a of 3.8 for adenine. It seems that the hydrogen bonding causes an hysteresis effect; the titration curve in one direction is not reproduced on back titration, as in the cytosine moiety of DNA[10]. The double protonation of the adenine ring has caused considerable delocalisation of the charge in the adenine ring, and has highly polarised[7,11] the N(1)–H, N(7)–H, C(2)–H and C(8)–H bonds so that they take part in bifurcated hydrogen bonds—or weaker bifurcated hydrogen interactions (Table 1). The C(2)–H and C(8)–H hydrogens have no such contacts in the neutral and anionic forms of gc^{6}Ade. In all these bifurcated bonds and weaker bifurcated interactions, the hydrogen atom lies close to the plane through the donor and the two acceptor atoms[12,13].

Balance between swelling pressure and collagen tension in normal and degenerate cartilage

ARTICULAR cartilage contains a high concentration of acid glycosaminoglycans (GAG), reaching 6% by wet weight and associated with fixed charge densities up to 0.2 mEq g^{-1}. This leads to considerable swelling pressure within cartilage, due to, first, the strongly non-ideal osmotic pressure, characteristic of polymer solutions, which increases sharply with concentration and, second, the ionic contribution, in accordance with the Gibbs–Donnan equilibrium. Ogston and Wells[1-3] have estimated the values of these two components and I have calculated them from my experimental data on cartilage[4,5]. The two components of swelling pressure are approximately of the same order of magnitude and can reach values as high as 1.7 kg cm^{-2} (refs 4 and 5). Since normal cartilage does not swell in solution, even when it is removed from the joint and cut into thin (250 μm) slices (lowest curve, Fig. 1), this implies that its high swelling pressure must be counteracted by considerable elastic forces within the collagen fibre network. It has been known for some time that the concentration of GAG gradually increases from the articular surface to the deep zone (for example, refs 6 and 7). A typical variation of total GAG content with depth, measured as fixed charge density, is shown in Table 1. I now suggest that this particular profile is adapted to the physiological function and mechanical properties of cartilage.

Table 1 Ionic components of swelling pressure corresponding to different values of fixed charge density

Distance below articular surface (mm)	*Fixed charge density (mEq per g of wet tissue)	†Ionic component of swelling pressure (kg cm^{-2})
0	0.05	0.16
0.25	0.10	0.45
0.75	0.15	0.8
1.75	0.18	1.7
2.25	0.20	2.1

*The figure for the surface concentration of charged groups was obtained by X-ray probe analysis[17]. The other figures were obtained by the tracer cation method[11] and verified by chemical analysis[5].

†The values of the ionic component of swelling pressure were calculated using Na$^+$ and Cl$^-$ partition data obtained experimentally for slices of human femoral head cartilage (my work with W. D. S. Freeman, in preparation), and a formula given by Katchalsky *et al.*[18], to estimate the fraction of osmotically 'active' counterions. Similar values were obtained when a procedure suggested by Wells[12] and based on Manning's approach[20] was used in the calculations.

First, it must be remembered that a high GAG content is essential to the load-bearing requirements of joints for it confers on the tissue low hydraulic permeability[8] and high swelling pressure[1]. It thus serves both to limit the amount of liquid lost when cartilage is loaded in compression (and hence the resulting creep), and to ensure the speedy "recovery" of cartilage during the "off-load" intervals in the walking cycle[4-5].

If, however, the GAG concentration were uniformly high throughout the cartilage thickness, right up to the interface with synovial fluid, there would be a steep osmotic pressure gradient across this interface. The local tensile stresses in the collagen fibre network oppose the local swelling pressure gradients at any point within the tissue, and so, at the surface, the collagen fibres would have to be under exceptionally high tension to oppose the very high osmotic pressure gradient which would be present there. In reality, the GAG concentration at the surface is at its lowest, rising to a broad peak in the middle zone. Table 1 shows the values of the ionic component of swelling pressure as a function of distance from the surface. A fairly even gradient of swelling pressure is observed in the tissue, with only a small fraction of the maximum pressure at the interface with synovial fluid. This grading of stresses, however, seems to be designed more as a protection against long term fatigue, since collagen fibres in normal cartilage do not disrupt instantaneously or allow any measurable swelling when thin slices from whatever zone are exposed to solution (as mentioned above and shown in Fig. 1, lowest curve).

In contrast, degenerate cartilage swells easily. It has long

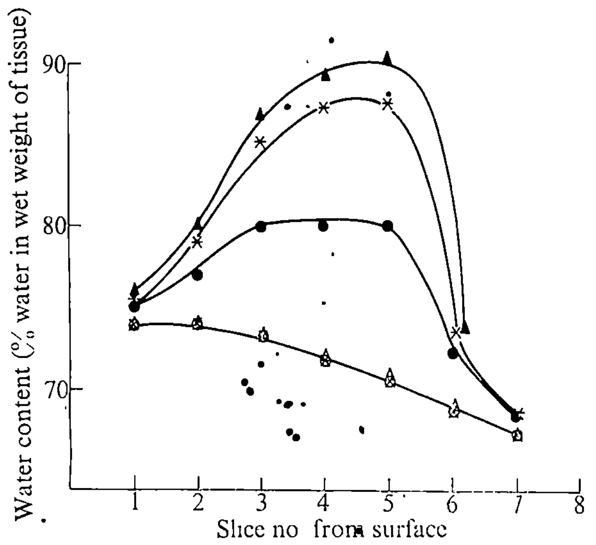

Fig. 1 Hydration in normal and degenerate cartilage. The moisture distribution in the chunk was obtained by slicing the latter on a freezing microtome into 250-nm slices and weighing these directly The subsequent swelling of the slices was determined by immersion in appropriate solution and weighing again after equilibration. Degenerate cartilage: ●, as cut; ▲, after soaking in 0.015 M NaCl; *, after soaking in 0.15 M NaCl Normal cartilage; ○, as cut; △, after soaking in 0.015 M NaCl; ×, after soaking in 0 15 M NaCl.

been known that one of the symptoms of cartilage degeneration is increased water content (for example, refs 9–11). This may seem surprising, for cartilage degeneration is usually accompanied by a loss of glycosaminoglycans. Few plausible explanations have been suggested for this paradox. I have suggested[11] that a failure in the elastic restraint of the collagen network enabled fibrillated tissue to swell to a higher degree of hydration in spite of the relatively low osmotic pressure of its decreased GAG content. I now present data in support of this hypothesis.

Figure 1 shows a profile of variation in water content with distance from the articular surface for both normal and mildly degenerate cartilage (my work with M. Venn, submitted for publication). In the normal cartilage, the water content seems to be little affected by the local GAG content. In degenerate specimens there is a distinctly different pattern, with a maximum in the middle zone, which I interpret as follows If the collagen network is partly damaged, its restraining effect on the swelling will be diminished and the hydration profile in cartilage should parallel its GAG content (which is known, in mildly degenerate tissue, to be rather low at the surface but still reasonably high in the middle zone (refs 11 and 12)). An intact collagen network is often still preserved in the deepest zone and thus there is no possibility of swelling in this region.

I further found that when a full depth chunk of surface-fibrillated cartilage is cut into 250-μm parallel slices, and these are immersed in buffered physiological saline (0.15 M NaCl), considerable swelling occurs in the slices from the middle zone, compared with their original water content (Fig. 1). This is consistent with the increased osmotic stress in these slices when exposed directly to isotonic saline solution, compared with the situation within the chunk. The swelling of middle zone slices was even more pronounced when they were immersed in a hypotonic solution (0.015 M NaCl), since the ionic component of the pressure differential was thus further increased (Fig. 1).

These results point to the fact that increased hydration in degenerate cartilage is due to damage of the collagen network and not, as suggested[13], to an increased fraction of so-called "bound water".

Finally, I wish to draw attention to a further implication of the above findings. *In vivo* the loss of GAG from the surface in an early stage of degeneration must, by this reasoning, lead to a steeper swelling pressure gradient in the middle zone, which should in turn lead to a greater stress on the collagen network there. It seems a reasonable supposition that fibres under tension are more liable to scission, whether by mechanical or enzymatic agents. I therefore suggest that once the surface layer of cartilage begins to lose its GAG, a self-perpetuating destructive process ensues in which successively deeper layers are exposed to gradual collagen disruption through GAG depletion.

It is still not known whether the primary event which leads to cartilage degeneration is glycosaminoglycan loss brought about enzymatically, with the damage to the collagen network following[14], or whether mechanical fatigue[15] is the direct cause of fibrillation, with the damaged collagen network subsequently enabling the proteoglycans to escape from the articular surface. But the observation that both in the early stages of an experimentally induced osteoarthrosis in the dog[16], and in some visually intact specimens of human osteoarthrotic cartilage removed for joint replacement (my work with M. Venn, submitted for publication), the water content is invariably increased, while the GAG levels remain normal, suggests (because of the casual association put forward here between the swelling of cartilage and a damaged collagen fibre network) that collagen fatigue and breakdown may be the earliest in a destructive chain of events.

Whatever the nature of the first step, it is obvious that early swelling of cartilage must also lead, through dilution of GAG in the tissue, to increased hydraulic permeability and decreased osmotic pressure[4], and thus must create an unfavourable mechanical environment in subsequent stages of the self-destructive process outlined here.

Growth of algal symbionts in regenerating hydra

BETWEEN 10 and 20 photosynthetic algae are maintained per digestive cell in green hydra, the freshwater polyp. In normal conditions the number of symbionts maintained within the host remains stable—the algae do not overgrow the host nor do the animals outgrow the algae[1]. In experiments described here we found that when the upper two-thirds of a hydra was removed, there was a pronounced increase in the number of algae per digestive cell in the remaining peduncle of the animal. The observed increase in algal numbers was not a function of starvation and could be abolished by grafting a head, from a donor animal, on to the peduncle. We believe that our experiments are the first to show that the reproduction of symbiotic algae may be influenced by the host and that the presence of a head, thought to be responsible for maintenance of polarity and other morphological phenomena in hydra[4], may also influence the reproduction of symbiotic algae.

We used a variant of the green hydra, referred to as the English strain. Animals were reared and maintained under a 12 h light/12 h dark photoperiod and fed *Artemia nauplii*[3]. Five experimental organisms were macerated together and a sample of the resulting cell suspension was examined under a compound microscope. The algae in 150 randomly selected digestive cells were counted[1,4].

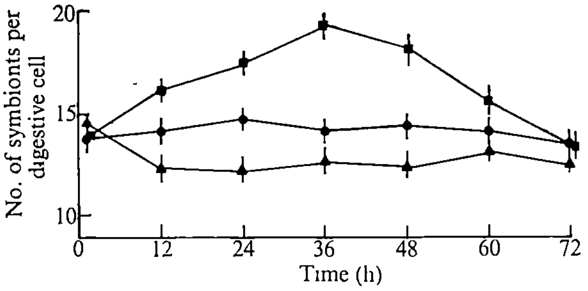

Fig. 1 Average number of algae per digestive cell from peduncle region of hydra at various times after removal of the upper two-thirds of the animal. Vertical bars show the standard error, $n = 150$ digestive cells. ■, Regenerating peduncle: analysis of variance indicates significant difference between points ($P < 0.001$). ▲, Peduncles removed from unfed animals at time of counting: analysis of variance indicates no significant difference between points ($P > 0.10$). ●, Peduncles with grafted heads: analysis of variance indicates no significant difference between points.

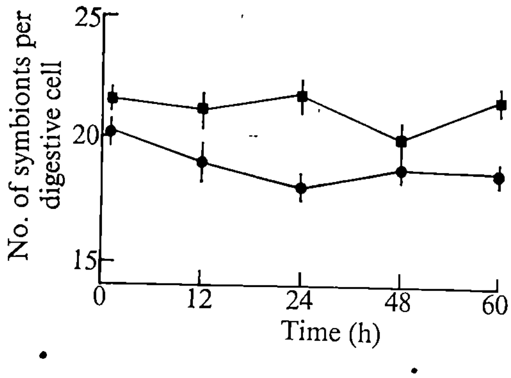
In our first experiment we removed the upper two-thirds (head, gastric and budding regions) of a group of hydra. At 12-h intervals after amputation, the algae per digestive cell were counted in the regerating peduncles. Green hydra normally maintains about 15 algae per digestive cell in the peduncle region. The regenerating peduncles did not eat throughout the experiment. Thus for controls, peduncles freshly isolated from unfed, intact animals were also analysed. Figure 1 shows that in regenerating peduncles the number of algal symbionts per digestive cell increased 25% from about 14 to 20 within 36 h of amputation of the upper two-thirds of the animal. After this increase in symbionts there was a decline in numbers per cell until the original level was established at 72 h, when the peduncle had regenerated the head and could feed. No change in algae per cell was observed in the control animals (Fig. 1*b*).

Fig. 2 Average number of algae per digestive cell from gastric region of hydra. Vertical bars show the standard error, $n = 150$ digestive cells. ■, Gastric region from animals after amputation of peduncle: analysis of variance indicates no significant difference between points. ●, Number of algae per digestive cell of gastric region removed from unfed animals at time of counting: analysis of variance indicates no significant difference between points.



To determine the possible influence of the head region on the growth of algae in the peduncle, we grafted heads from donor animals to the amputated peduncles. As before, these organisms were not fed and were analysed every 12 h. As Fig. 1 shows, there was no increase in the number of algae per digestive cell in peduncles with grafted heads. Furthermore, there was no change in the number of algae per digestive cell in the upper gastric region (with heads) after amputation of peduncles (Fig. 2). These cells in the upper region normally contain approximately 20 symbionts.

Apparently the presence of a grafted head region prevented or inhibited the algal increase observed in the absence of the head region. It has been suggested that the head region is the site of morphogenetic substances which maintain the normal polarity and organisation of the animal[5]. Our results suggest that factors associated with the head inhibit algal reproduction in the peduncle also. These factors might act directly on the reproductive processes of the algae or indirectly through processes in the host's digestive cells in which the symbionts reside. When amputated, the peduncle tissue is removed from the influence of the head and the symbionts, now released from inhibition, begin multiplying.

It is not clear how the number of algal symbionts is reduced after the initial increase (Fig. 1). A possibility is that subsequent host cell division causes parcelling of the symbionts among the daughter digestive cells. The relationship between the head and animal cell division in the peduncle is unknown.

THE Scottish intellectual enlightenment in the eighteenth century is rightly attracting attention among current historians of science in the US. A few months ago we had from Richard Olson an interesting book on *Scottish Philosophy and British Physics 1750–1880* (*Nature*, **258**, 285; 1975) on the effects of the Scottish common sense tradition on the development of British physics. And now we have from A. L. Donovan of the University of West Virginia a study of the interaction of two great Scots chemists of the enlightenment, William Cullen (1710–1790) and his pupil Joseph Black (1728–1799).

Donovan gives a good picture of the intellectual state of Scotland and its universities in the eighteenth century, and one of his aims is to demonstrate that "the advancement of scientific knowledge was a matter of both philosophical and practical concern in eighteenth century Scotland". He was drawn to study the question of how Black came to discover 'fixed air' (carbon dioxide) and this in turn led him to investigate William Cullen, with whom Black worked in Glasgow after graduating in arts and medicine. This was at about the time when, thanks largely to Cullen, chemistry was becoming a university study in its own right instead of being merely part of natural philosophy on the one side or medicine on the other.

If anything, Black was more of a natural philosopher, as shown by his work on specific heat and latent heat; but it was the medical need to find a solvent for renal stones that led him to recognise that chalk contained 'fixed air' which could be released as a gas by heat or acids, but which could also be transferred from one substance to another in solution without being released as effervescence. Donovan has gone to much scholarly trouble to trace this development in Black's mind—perhaps all the more interesting because it occurred against the background of Black's acceptance of the Phlogiston theory which Lavoisier's work later forced him to abandon.

Joseph Black (1728–99) by David Martin

Photo: University of Edinburgh

Black's influence, of course, extended beyond chemistry, and the last chapter of the book surveys his interaction and friendship with John Robison and James Watt, to whom Black's concept of latent heat was especially relevant. And when Watt invented the condensing steam engine Black (who in later life weighed every golden guinea that his students paid him in fees to check that they had not been cheating by filing the coins) lent him one thousand pounds to develop the engine.

Donovan has produced a useful, detailed, and well annotated study of an important phase of the Scottish scientific heritage. ☐

Immunology in vogue

A. J. S. Davies

The Immune System: A Course on the Molecular and Cellular Basis of Immunity. By M. J. Hobart and Ian McConnell. Pp. xxiii+357. (Blackwell Scientific: Oxford and London; Lippincot: Philadelphia and Toronto, 1975.) £5.00

SURELY the function of a book is communication between the author and reader. In this respect far too many contemporary scientific texts are deficient. They seem to operate on the assumption that the message is there—if you look hard enough. Aggregates of papers each by a different author with little editing or editorial comment are particularly prone to this elitism. It is then a happy event to find this book. It arose out of the course in advanced immunology sponsored by the Department of Immunology at the Royal Postgraduate Medical School and contains an amplification of the lecture notes. There has, however, been much useful editorial grading and cross-linking.

There are four major sections, each containing several chapters, on immunochemistry, immunobiology, immunogenetics and immunopathology. Each section has a chatty editorial introduction by no means as prolix as their designation 'preambles' would suggest. The range of topics is considerable although by no means comprehensive. In the immunopathology section for example, there are chapters on the so-called tumour immunology, immunodeficiency diseases, and autoallergic conditions but nothing on parasitic disease.

The illustrations, with the exception of one or two rather indeterminate electron micrographs (for example, on p60) are first class and provide an important visual element to the verbal complexities of contemporary immunology.

Following the present vogue, the book is predominantly concerned with cells and molecules and, with the exception of the illustrations of T and B areas on p210, there is hardly any histopathology. The approach of the synthesist in immunology is long overdue, and although there is a good chapter on the structure and function of the lymphoid system by McConnell this is not enough for my taste. A section on immunopathology can hardly be complete with no consideration of reactive changes in lymphoid organs. The book as a whole is so nearly comprehensive as to make consideration of remedy of these minor deficiencies worthwhile.

The book throughout is very readable, and the intention of the editors to communicate with their readers is made clear and is resoundingly successful.

In an age when new books tend to be greeted with a groan by overladen minds here is one for your personal perusal. Don't leave it to the library—get one yourself, it's a splendid book. ☐

Methodical investigation of dynamic systems

Introduction to Mathematical Control Theory. (Oxford Applied Mathematics and Computing Science Series.) By Stephen Barnett. Pp. viii+264. (Clarendon: Oxford; Oxford University: London, 1975.) £5.75 net.

THERE has recently been a shift of interest in control theory from engineering towards applied mathematics. Although this reflects growing awareness of the range and depth of mathematical problems which have been formulated in terms of modern control theory it also sadly reflects a growing disillusionment on the part of the professional engineer at the failure of control theory to realise but a small fraction of what was promised a decade ago. In recent years there has been a significant return to linear system concepts to formalise the techniques necessary for analysing systems in which the numbers of control variables are large. This has led naturally to the use of state vectors and matrix system operators to describe the dynamic performance of systems. It is here that the first difficulties arise since not only are matrix equations often difficult to manipulate, but they do not provide a physical insight into the nature of the control problems which the semigraphical older methods of control theory provided.

There clearly is a need for basic textbooks which can introduce the newer aspects of control theory and, if possible, link them with more established techniques. The audience would include applied mathematicians new to the control field, as well as students and practicing engineers. Stephen Barnett's book roughly supplies this need. Engineers will not find it an easy book to read since matrix algebra at this level is a demanding discipline. This is not made easier by the concise treatment given to many theorems but this is unavoidable in a work of this length. The reader will be struck, however, by the symmetry and compactness of the general theory which is beginning to evolve. The mathematician will find unusual outlets for studies in stability theory and the calculus of variations.

Although the book is by no means exhaustive in its range, it does cover a basic related set of topics and prepares the ground for further study. There are numerous worked examples and exercises but, as in most control textbooks, these describe problems which are almost trivial from an engineering point of view. It is argued that once the concepts have been mastered the extension to worthwhile problems is straightforward and is considerably aided by computational methods. It is of course here that the rift between theory and practice occurs. The formulation of real problems in terms of linear dynamic models, or often in any mathematical form, is difficult if not actually meaningless. Solutions, except in terms of empirical effort, are expensive to obtain and may then be impractical to realise. In spite of all this, sensibly applied control theory has much to offer in providing a framework for the methodical investigation of dynamic systems. This small but scholarly book will help to build such a framework.

J. M. Nightingale

Showing the flag

Geodynamics Today: A Review of the Earth's Dynamic Processes. (Sponsored by the British National Committee for Geodynamics for the Inter-Union Commission on Geodynamics.) Pp. 197. (The Royal Society: London, 1975.) £2.75 UK; £2.85 Overseas, including postage.

THE Geodynamics Project (1972–1977) is a loosely-coordinated international program of research into the dynamics and dynamic history of the Earth with emphasis on phenomena affecting surface and near-surface processes and structures. In 1973 the US Geodynamics Committee published, at no charge, a highly regarded and more or less definitive 235-page report on the scope and objectives of the Project. Soon after it appeared, the British National Committee for Geodynamics decided that something more than a preliminary British statement (published by the Royal Society in 1971) would be appropriate; and the result, published more than halfway through the Project, is *Geodynamics Today.* It is a sad reflection that in inflation-ridden 1970s Britain one has to pay to view the flag.

And the flag is a bit tatty at that. In this loosely-coordinated non-international program of 23 short state-of-the-art reviews on geodynamics some authors have dealt in generalities, others have resorted to detail; some have emphasised the past-to-present, others have concentrated on the present-to-future; some have included references and/or diagrams, others have gone for words only; some have put their heart into it, others have not. The result is a hotchpotch in which, the overriding geodynamic theme apart, subjects are linked only by virtue of the active or passive interest of the British scientists concerned. Nevertheless, the topics cover a wide range of geodynamic problems; and if no-one will wish to read everything, there is something here for almost everyone.

It is impossible to mention every subject covered and difficult to select a few. But of particular interest, because they are concerned with expanding themes of general consequence, are J. Sutton on the geodynamics of the Precambrian, E. R. Oxburgh on plate collisions past and present, I. G. Gass and others on the origin and emplacement of ophiolites, W. S. Fyfe on the influence of the hydrosphere on magma and D. H. Tarling on pre-Mesozoic palaeomagnetism. Also worthy of note, but for a different reason, is the article by N. N. Ambraseys, one of the few people to recognise the importance of historical seismicity studies, especially in the scientifically unpopular Mediterranean region.

If one general point emerges from this collection, or part of it, it is that British Earth scientists of various persuasions are particularly well placed, by inclination and experience, to lead the assault on the problems of pre-Wegenerian geodynamics. It is to be hoped that the money will be available for them to do so.

Peter J. Smith

Lunar Mineralogy. By Judith W. Frondel. Pp. x+323. (Wiley-Interscience: New York and London, October 1975.) £11.20.

THE ending of the Apollo and Luna missions marks a significant turning point in the development of lunar science Over the past five years efforts have concentrated on frantic reconnaissance and sample analysis in preparation for future missions, but now the pace has changed and problem-orientated studies and a more thoughtful evaluation of published data seem to be the most obvious of immediate future developments. In this situation the appearance of a book of this type is particularly valuable. About 850 pounds of rock were recovered in the Apollo programme, but it is important to remember that of this only about 10% has been extensively examined; approximately 20,000 individually identified samples remain available for future study.

This book has grown from two editions of a *Glossary of Lunar Materials* which the author prepared for distribution by NASA to principal investigators of the Apollo programme. It is arranged in the manner of Dana's *System of Mineralogy* and summarises all lunar mineralogical data published up to and including the Fifth Lunar Science Conference in March 1974. The author's task has been aided by the Earth's satellite, for rich repositories of rare and spectacular minerals such as pegmatites, true granites and hydrous vein deposits are conspicuously absent in the Moon; the rocks remain in a highly reduced state and there is a marked depletion in elements more volatile than iron. It is not surprising therefore to learn that only 60 valid and 14 tentatively identified mineral phases have so far been reported compared with about 2,200 on Earth, and there are no lunar diamonds.

Individual minerals are described in eleven systematic chapters; the treatment here is concise but adequate, and each section gives a good account of how particular minerals occur in lunar rocks. There are useful tables with selections of mineral analyses, photomicrographs wherever possible, and abbreviated references The wisdom of including here abbreviated optical and X-ray data on minerals such as olivines is questionable; the photomicrographs and specimen photographs are of a high quality, and the eye is captivated by the beautiful scanning electron microscope photographs of iron crystals deposited in vugs. The systematic chapters are preceded by an excellent 16-page introduction which summarises the history and petrology of the lunar surface, this section can be thoroughly recommended to amateurs. With these in mind, however, it is disturbing to read on page 7 that "Total and partial melting, a relatively insignificant feature on Earth, is important in the petrogenesis of the lunar highlands".

The author and publishers are to be congratulated on the high standard of production The book will be a standard reference for many years to come, and will be particularly valuable for those who have not worked on lunar minerals. The main text is supported by a bibliography, simple index and appendices which list the samples mentioned in the text and explain the sample-numbering system.

I. D. Muir

Lunar science

Lunar Science. A Post-Apollo View—Scientific Results and Insights from the Lunar Samples. By S. R. Taylor. Pp. xix+372. (Pergamon: New York and Oxford, 1975.) $16.50, £6.90.

THE technological *tour-de-force* in landing men on the Moon in the six missions Apollo 11, 12, 14, 15, 16 and 17 and the drama of Apollo 13—in particular the extreme sophistication of the systems control—has perhaps overshadowed the scientific achievements in the study of the returned lava, breccia and soil samples and the observations from experimental apparatus, some still functioning on the Moon. How appropriate it would be in this bicentennial year of the US if NASA produced a history of this unprecedented scientific project: by what alchemy did imaginative planning emerge from committees of scientists and administrators in Washington. But in some ways the very triumph of the scientific collaboration has been buried in vast conference proceedings; and it has been left to Dr Ross Taylor to give a most admirable answer to the question insistently asked "What really did this project discover about the Moon?".

Many of the conclusions reached or reinforced by evidence brought back by the Apollo project are set out clearly by Dr Taylor, and the book is a remarkable one: no scientist could fail to be fascinated and even those most learned about the Moon will learn something more. One miracle, however, was not achieved by the planners of the Apollo project: in spite of all attempts it has not entirely succeeded in bringing about an easy communication between petrologists and geochemists on the one hand and geophysicists on the other. In the many lunar conferences once the former begins talking about ferropseudobrookite and hedenbergite—ferrohedenbergite, the eyes of the latter become glazed; and when the latter begin speaking of electromagnetic transfer functions and magnetic Reynolds numbers, the conference room empties noticeably. In his treatment of the physics of the Moon, mainly in chapter 6 (only 29 pages), Dr Taylor falls from the high standard elsewhere.

Yet it was in this field that three of the most surprising and unexpected discoveries were made—positive anomalies in gravitational field occurring over the circular maria, remanent magnetisation of the returned specimens, along with magnetic anomalies in the lunar crust and moonquakes occurring predominantly at apogee and perigee. Dr Taylor does not treat these discoveries—fundamental to any understanding of the Moon's interior and its evolution—in the depth they deserve. For example in lunar magnetism he relies on a review, which he says provides "appropriate skeptical comments on current theories." Although some ideas which have been suggested to explain this unexpected finding are plausible—Velikovsky's prediction that the lunar surface was magnetised in 3,000 BC—some theories merit serious consideration. But some inconclusiveness is only to be expected when a new phenomenon is discovered. Observations that can be immediately understood in terms of currently accepted orthodoxy are not of so much interest as those which open up new approaches.

The fundamental significance of the non-hydrostatic figure of the Moon is ignored and thermal convection occurring by solid-state creep in its interior is not mentioned. The essential requirement of a theory of mascons—that is, that extra mass, whether lava or not, must be brought by lateral transport into the circular mare area—is not made clear. The implications of the remarkable correlation between the occurrence of moonquakes and the tides, and the analogous effect with regard to the enigmatic lunar transient events, are also not brought out.

S. K. Runcorn

obituary

Professor W. Ehrenberg, who died on November 19, 1975 at the age of 74, was born and brought up in Berlin. When a boy, he fell a victim to poliomyelitis which left him severely handicapped, but he never allowed this to impede his work in experimental physics, to which he transferred his main interest immediately after gaining his Ph.D. from Heidelberg in 1924. In 1926 he published with H. Mark and G. von Susich some now classic papers in which the natural width of the K X-ray lines was demonstrated and the two-crystal X-ray spectrometer proposed and analysed. With Ewald he conducted an experimental verification of the predictions of the latter's dynamical theory of X-ray diffraction. This and other X-ray experiments were carried out first in Berlin and later at the Technische Hochschule in Stuttgart, where he also made contributions on the diffraction of low-energy electrons and on the wave-mechanical theory of electrical contracts.

In 1933, with other refugees from the Nazis, he joined Professor Blackett's group at Birkbeck College, University of London, where he published papers on cosmic rays and neutron physics. Between 1936 and 1945 Ehrenberg worked at the EMI research laboratories, mainly on problems concerned with radar and the development of television tubes. Although possibly not so fruitful from a scientific point of view, this period of industrial research nevertheless gave him wide experience of electron beam devices and related techniques, which were to prove of considerable value in his later work. During this period he privately embarked on new studies; a paper on entropy and irreversible processes dates from this time, and thermodynamics became an abiding interest.

In 1945 Ehrenberg returned to Birkbeck as one of Professor Bernal's six Nuffield research fellows: his rôle was to apply electron optical and X-ray optical techniques to problems of crystallographic instrumentation, while remaining free to supervise research in other fields. During the next decade he built up a flourishing research group at Birkbeck College. For him and his students it was a period of intense and exciting activity. In 1949 he published, with R. E. Siday, a theoretical paper on electron optics in which they reached the surprising conclusion that electron interference can be affected by the presence of a magnetic flux even if the electron paths do not pass through a magnetic field This idea was independently put forward ten years later by Aharonov and Bohm and was then verified experimentally by R G. Chambers.

On the experimental side he contributed during these years to X-ray optics, particularly to the focussing of X-rays by total reflection at glancing angle from slightly curved surfaces, a development from his experiments in Berlin some 20 years before; but he found the usefulness of the technique to be limited by the excessively stringent requirements for smoothness, a difficulty that has recently been overcome by a group at the National Physical Laboratory, including his former student A. Franks. Another interesting development was the fine focus X-ray tube, devised by him in collaboration with W. E. Spear. The instrument was subsequently marketed by Hilger and Watts and found application in X-ray crystallography. It was characteristic of Ehrenberg that the royalties were assigned to a fund for the development of scientific instruments.

The immediate post-war years also marked the beginning of Ehrenberg's pioneering studies on the conductivity induced in insulating solids under electron bombardment, which eventually was to become his major concern. His 1954 paper with F. Ansbacher is still widely quoted and was one of the first detailed investigations in this field, which he and his collaborators continued to develop in subsequent years. His major work *Electronic Conduction in Semiconductors and Metals* was published in 1958 by Oxford University Press and contains the fruit of much original thought on the subject.

His appointment in 1951 to a Readership at Birkbeck College was followed in 1962 by a Chair of Experimental Physics; two years later, Ehrenberg became head of the Physics Department. Administrative responsibility thus came late in his career, but he applied to its problems the same penetrating and flexible mind that had enabled him to redirect his interests first from philosophy to physics and then successively between several fields of specialisation. After retirement in 1968 he continued to examine, to supervise research and to participate actively in colloquia. In his final years he brought to bear on the preparation of a book on *Cause, Necessity and Chanc* his combined knowledge of thr classical philosophy, science ar languages.

Werner Ehrenberg was a remarkable man, who showed great courage in facing and overcoming the many difficulties caused by his physical disability. His humanity, enthusiasm, experimental ingenuity and physical insight were an inspiration to all, and especially to his research students, who held him in deep affection for his total devotion to the search for truth and for the generosity and imagination with which he would enter, often at a moment's notice, into a discussion of almost any problem on the enquirer's terms. His friendship was as unforgettable as it will be irreplaceable.
